PREFACE

Science may be defined as systematized knowledge. Since the practice of surgery defies exact formulation, it must remain an art, or a system of knowledge made efficient by mental and physical skill. Obviously, the more perfect the scientific part of surgery becomes, the more useful and beneficial will be the art of surgery.

The basic sciences then must be learned, reviewed, and applied to the clinical practice of medicine. This is doubly true in the application of surgical measures for the care and cure of disease processes. A knowledge of embryology enables the surgeon to understand congenital anomalies; anatomy is necessary in diagnosis and operative procedures; histology helps him understand pathological states; and etiology often teaches him how to avoid and correct them. Applied physiology is paramount in the practice of surgery. Such states as anoxia, shock, hemorrhage, endocrine imbalance, and subhydration are but a few of many examples that may be mentioned. A knowledge of biochemistry is necessary for the proper evaluation of such states as acidosis, alkalosis, tetany, and calcium imbalance and may point the way for a clearer concept of the formation of biliary and renal calculi. The sterols alone may open the door to the secrets of such diversified conditions as nerve and endocrine function, carcinoma, biliary calculi, and cardiac disease.

This book is written with the idea of correlating the basic sciences with the fundamental principles of surgery. Upon such a foundation can be erected the structure of clinical surgery—etiology, diagnosis, symptoms and signs, prognosis, and treatment, even to the minutest detail of technique.

The body of the book carries the "conquered ground" of surgical diseases; however, the correlated facts, the physiology, and even the unconquered experimental fields from which the ultimate truths will emerge have not been neglected. In both instances the discussion is relatively brief; however, if this book accomplishes that which the medical teacher tries to achieve, it will inspire the student to search through the selected references for more complete information.

The references quoted have been used extensively. Some of the data are given verbatim; most are interpreted by the author in the light of his own experience or in the experience of his advisors. It is his desire that full credit be accorded the many books, journals, and personal communications included herein.

If at times the text seems dogmatic, it is because the student must have a definite course charted for him so that he be spared the ordeal of drifting aimlessly among the waves of conflicting opinion. This is necessary until he may acquire surgical judgment—that intangible, essential attribute which gradually evolves through direct personal knowledge, procured by astute observation, actual practice, and constant persistent research.

The response to my first work, *Synopsis of the Principles of Surgery,* has encouraged me to produce this new book. Some information which appeared in the first book as "conquered ground" has been relinquished. Much that appeared in the footnotes as the "unconquered territory" of the experimenter has been won. Still more that was predicted, fortuitously perhaps, as the possible result of future investigation, has come true. These changes, flavored by the helpful and constructive criticisms of colleagues and reviewers, have been made in the pages that follow.

This new text deals chiefly with fundamental principles of surgery and is not intended as a monograph on every surgical specialty. However, surgical techniques are discussed. If a proper perspective is to be achieved, a good surgical specialist must first be a good general surgeon.

The writer of a text is presumed to have an intimate knowledge of the subjects he describes. This is the result of experience in most instances, but in many cases he must turn to other writers and observers for help. The references are designed to guide the student to proper authority in each particular field. The more highly specialized branches of surgery need special interpretation. To secure these I have turned to competent members of the respective groups for help and advice.

To my friends and advisors and to my loyal students, interns, and residents I give my sincere thanks. A few names of those who helped in the production of this book should be given special mention: Dr. Frank Forry, Dr. Clyde G. Culbertson, Dr. John L. Arbogast, and Dr. Amos C. Michael, of the Department of Pathology, have aided in procuring and properly interpreting pathological specimens; Dr. R. M. Harger gave splendid suggestions in the preparation of the chapter on acid-base balance; Dr. George J. Garceau gave good counsel on the chapter relating to orthopedics; and Dr. John A. Campbell selected and interpreted interesting x-ray films.

Dr. Edward J. Berman acted as my severest critic on the context and contents of the book, and in addition he aided materially my attempts to employ English that fulfills the requirements of proper syntax and semantics. Dr. Joseph F. Ferrara helped in the tiresome but important task of reading the proof.

Dr. Bertram S. Roth has provided valuable information concerning blood dyscrasias in infants and children. He has also answered many

questions relating to such vital functions as oxygen requirements, water *balance, and protein metabolism in infants.*

Since illustrations reveal more than words, Mr. J. F. Glore, medical artist, deserves special praise for the splendid drawings, diagrams, and photographs.

The typing of a book is a huge task in itself, but when in addition it requires a deciphering of the hieroglyphics of poor penmanship, it becomes a mountainous detour—such was the task of Mrs. Cecilia Suess, my meticulous stenographer, to whom I am grateful.

Mrs. Mildred Chandler, my faithful secretary, aided in reading the typewritten pages and relieved us of a mass of detail in the execution of this involved work.

JACOB K. BERMAN.

HISTORICAL REVIEW

A book on the principles of surgery must not be limited to any one particular branch. It must contain the fundamentals of medicine as applied to surgical pathology and clinical surgery. It has been aptly said that the best textbook of surgery is a good textbook of medicine.

The historical approach to a subject enhances our understanding of it. If we wish to appreciate America, we must know some of the historical background of this country or our appreciation is limited. If we wish to approach a certain surgical subject, we must know, at least in a superficial way, what preceded present-day knowledge. As Osler put it, "The past is a good nurse, especially for the weanlings of the fold."

Much of the historical review will revolve about individuals. This is true because of the separation of men and distant places. Travel was limited, printing came later and even then great distances separated men. Today we speak of a trend which is broad and inclusive. The world is indeed one world as Wendell Willkie has put it. Men simply represent such movements as are occurring, whether they be in medicine, sociology, or government. They cannot, as individuals, initiate control, alter, or stop them. This is the reason for the lack of contemporary names in the present century.

Prehistoric man had some knowledge of surgery. He treated disease mostly by incantation and all sorts of superstitious practices; occasionally an archeologist uncovers a body of an early man that has a surgical trephine opening in the skull. Following the prehistoric period comes what Garrison calls the period of Egyptian and then Sumerian and Oriental medicine (4500-3000 B.C.). Much information concerning this time is obtained from Ebers' *Papyrus* (1500 B.C.). This document was discovered by George Ebers at Thebes in 1872. The code of Hammurabi (2250 B.C.) is also an important contribution. This includes Babylonian and Chinese practice and some Biblical laws. Although their knowledge was very primitive, some of their teachings are still good. They practiced quarantine. Their moral and ethical laws are still the standard of the civilized world. In this period they knew of leprosy but they did not know its etiology. If we read the book of Leviticus we find that a leper is unclean: he must be isolated and no one must enter his house until he is

GENERAL CONSIDERATIONS OF SURGICAL PRINCIPLES

Chapter 1

HISTORICAL REVIEW

A book on the principles of surgery must not be limited to any one particular branch. It must contain the fundamentals of medicine as applied to surgical pathology and clinical surgery. It has been aptly said that the best textbook of surgery is a good textbook of medicine.

The historical approach to a subject enhances our understanding of it. If we wish to appreciate America, we must know some of the historical background of this country or our appreciation is limited. If we wish to approach a certain surgical subject, we must know, at least in a superficial way, what preceded present-day knowledge. As Osler put it, "The past is a good nurse, especially for the weanlings of the fold."

Much of the historical review will revolve about individuals. This is true because of the separation of men and distant places. Travel was limited, printing came later and even then great distances separated men. Today we speak of a trend which is broad and inclusive. The world is indeed one world as Wendell Willkie has put it. Men simply represent such movements as are occurring, whether they be in medicine, sociology, or government. They cannot, as individuals, initiate control, alter, or stop them. This is the reason for the lack of contemporary names in the *present century*.

Prehistoric man had some knowledge of surgery. He treated disease mostly by incantation and all sorts of superstitious practices; occasionally an archeologist uncovers a body of an early man that has a surgical trephine opening in the skull. Following the prehistoric period comes what Garrison calls the period of Egyptian and then Sumerian and Oriental medicine (4500-3000 B.C.). Much information concerning this time is obtained from Ebers' *Papyrus* (1500 B.C.). This document was discovered by George Ebers at Thebes in 1872. The code of Hammurabi (2250 B.C.) is also an important contribution. This includes Babylonian and Chinese practice and some Biblical laws. Although their knowledge was very primitive, some of their teachings are still good. They practiced quarantine. Their moral and ethical laws are still the standard of the civilized world. In this period they knew of leprosy but they did not know its etiology. If we read the book of Leviticus we find that a leper is unclean: he must be isolated and no one must enter his house until he is

ing or "sweating" through. He was a great deductive thinker. He would sit at a desk and put down a statement and work from there to a logical conclusion, but he also used inductive methods.

The deductive method of reasoning goes from the universal to the particular, from all to some, from the whole to its parts. It analyzes a premise and then proves it to be correct. This is known also as *a priori* logic, meaning the hypothesis that came before. The objection to this type of reasoning is that the major premises may be wrong, yet the logic sound, forcing the reasoner to a fallacious conclusion. Such reasoners are known today as sophists. (The original sophists were profound scholars.)

Induction is reasoning from the observed parts to a whole, from particulars to generals. It synthesizes the results of experimentation and discovery. This is also known as *a posteriori* logic. We must observe carefully and, if necessary, experiment in the laboratory, then synthesize our findings, and finally from all known facts we come logically to the correct conclusion.

Byzantine Period (A.D. 476-732). "A period known for its extreme luxury, licentiousness, profligacy and lack of accomplishment." "Byzantium is now known as Istanbul. With the downfall of the Roman Empire, Eastern scholars began to pour into Europe. **Paul of Aegina** (A.D. 625-690) stands out during this period. He was a surgeon. He knew of lithotomy, trephining, tonsillectomy, paracentesis, mastectomy, eye surgery, and military surgery. He knew how to pull teeth; he is said to have insisted that a dental forceps be made of soft lead. Did he think there could not be much wrong with a tooth if it took strong iron forceps to extract it? Or conversely, did he believe that if the tooth were dead and infected it would act as a foreign body and become loose so that its removal could be accomplished easily?

The Dark Ages (A.D. 476-1000).

This was the *Age of Feudalism* (from *feodum* or *feudum*, a fee or fief) which came into existence because individualism afforded no protection to life or property and because decadent monarchies were too loosely organized to give such protection. Consequently, the feudal lords came into power and the strongest and most powerful individuals took over the land and became the local rulers. The rest of the populace became vassals and serfs who banded together and worked under the lord in return for his protection. Feudal states were formed and feudalism remained until the medieval period, when kings arose from their previous lethargy, took back some of their territory, and gave royal titles to the feudal lords. All medical papers were written in Latin so that secular knowledge would not undermine the ecclesiasticism which prevailed. Men kept their "knowledge" to themselves. There was an air of mystery around the physician. The church helped during these Dark Ages. The monks did some experimental work in their monasteries which did not come to light until later.

Books were scarce, scholars were few and timid, and knowledge and learning were at a standstill. Physicians still believed in Galenic medicine, although Galen was more often wrong than right. Five hundred years were wasted so far as the development of medicine was concerned.

The Medieval Period (1096-1438) showed some progress. Men spoke of "laudable pus." As we shall see in Chapter 3, this term is still accurate

well. Then the priest will order the destruction of that house. They knew of certain surgical operations, although the Bible seldom speaks of any except circumcision.

Ritualistic circumcision was usually done on the eighth day of life and this custom is still retained. The reason for this practice was probably based on the observation that hemorrhage was more likely to occur if the operation were done earlier. It is now known that at birth and for about six hours thereafter the prothrombin level is normal. Apparently the reserve of this substance is limited and at twenty-four hours reaches a low level. This is due to a lack of vitamin K, which is not synthesized in the intestine until the infant begins to take food. Although bacteria are found in the colon within eight hours after birth, they probably are not present in sufficient numbers to produce this essential vitamin.

Greek medicine played a very important role in medical development. *Aesculapius,* who lived about 3000 B.C., is called the god of medicine. The Greeks thought he was a living personality. He is now thought to be a mythical figure, the son of Apollo and Coronis. He was trained by Centaur, who was half man and half horse. He antagonized Zeus, the god of gods, who slew him. He had two daughters, Hygeia and Panacea. Hygeia (prevention of disease) was known as the goddess of health; Panacea (derived from the Greek work "all-healing") is today used to describe a cure-all in medicine or treatment.

Hippocrates (460-370 B.C.) is held to be the father of medicine. He was a real character. Every student of medicine should read the notes and comments of Hippocrates and his sayings. He taught by aphorisms or maxims.

An aphorism is a concise statement of principle; a maxim, of medical art.

This is an excellent pedagogical method and will be used wherever possible in this book. It is difficult because many parts of medicine do not lend themselves to such synthesis. Hippocrates knew the many viscissitudes of medicine when he said: "Life is short, and the Art long; the occasion fleeting; experience fallacious, and judgment difficult."

Celsus lived during the reign of Tiberius Caesar. He was probably not a physician, but he wrote extensively on medical subjects. His *De Re Medicina* was one of the first books printed in the Renaissance (1478). It consisted of eight books; the fourth contains the four classical signs of inflammation (Chapter 10). The seventh contains the first account of the use of the ligature.

Galen (A.D. 131-201) (Greek physician in Rome) was a great man. He was so great that for a thousand years after his death medical men still preached and taught some of his correct as well as erroneous views. Many of his teachings were right. For example, he knew that the arteries contain blood and not air as was previously taught. He described inflammation and distinguished between arterial and venous blood. He thought, however, that blood passed from one side of the heart to the other by seep-

ing or "sweating" through. He was a great deductive thinker. He would sit at a desk and put down a statement and work from there to a logical conclusion, but he also used inductive methods.

The deductive method of reasoning goes from the universal to the particular, from all to some, from the whole to its parts. It analyzes a premise and then proves it to be correct. This is known also as *a priori* logic, meaning the hypothesis that came before. The objection to this type of reasoning is that the major premises may be wrong, yet the logic sound, forcing the reasoner to a fallacious conclusion. Such reasoners are known today as sophists. (The original sophists were profound scholars.)

Induction is reasoning from the observed parts to a whole, from particulars to generals. It synthesizes the results of experimentation and discovery. This is also known as *a posteriori* logic. We must observe carefully and, if necessary, experiment in the laboratory, then synthesize our findings, and finally from all known facts we come logically to the correct conclusion.

Byzantine Period (A.D. 476-732). "A period known for its extreme luxury, licentiousness, profligacy and lack of accomplishment." "Byzantium is now known as Istanbul. With the downfall of the Roman Empire, Eastern scholars began to pour into Europe. **Paul of Aegina** (A.D. 625-690) stands out during this period. He was a surgeon. He knew of lithotomy, trephining, tonsillectomy, paracentesis, mastectomy, eye surgery, and military surgery. He knew how to pull teeth; he is said to have insisted that a dental forceps be made of soft lead. Did he think there could not be much wrong with a tooth if it took strong iron forceps to extract it? Or conversely, did he believe that if the tooth were dead and infected it would act as a foreign body and become loose so that its removal could be accomplished easily?

The Dark Ages (A.D. 476-1000).

This was the *Age of Feudalism* (from *feodum* or *feudum*, a fee or fief) which came into existence because individualism afforded no protection to life or property and because decadent monarchies were too loosely organized to give such protection. Consequently, the feudal lords came into power and the strongest and most powerful individuals took over the land and became the local rulers. The rest of the populace became vassals and serfs who banded together and worked under the lord in return for his protection. Feudal states were formed and feudalism remained until the medieval period, when kings arose from their previous lethargy, took back some of their territory, and gave royal titles to the feudal lords. All medical papers were written in Latin so that secular knowledge would not undermine the ecclesiasticism which prevailed. Men kept their "knowledge" to themselves. There was an air of mystery around the physician. The church helped during these Dark Ages. The monks did some experimental work in their monasteries which did not come to light until later.

Books were scarce, scholars were few and timid, and knowledge and learning were at a standstill. Physicians still believed in Galenic medicine, although Galen was more often wrong than right. Five hundred years were wasted so far as the development of medicine was concerned.

The Medieval Period (1096-1438) showed some progress. Men spoke of "laudable pus." As we shall see in Chapter 3, this term is still accurate

(although with a different meaning) in the light of modern studies. Medical men looked down upon surgery with disdain and they looked upon the barber-surgeon as a craftsman, which indeed he was.

The barber-surgeon did two things; blood letting and "cutting" for stone. The modern barber still displays the red and white striped pole (symbolic of an extremity with blood flowing in spiral fashion).

Today surgery has come to be the *chief form of medical treatment*. In this respect, it is very much as the science of bacteriology was before it developed to its present degree. Books on botany and biology formerly had only one paragraph on bacteria. So it was with surgery in relation to medicine. *Today surgical knowledge has accumulated so fast that it equals* its parent subject. But it still must be studied in its proper relationship. The surgeon must be a good medical man first and then a surgeon in addition. He has two responsibilities instead of one.

The Renaissance or the Revival of Learning (1453-1600).

Outstanding events of this period were the fall of feudalism, migration of Greek scholars to Europe, the invention of crude methods of printing, and the discovery of America in 1492. The Chinese knew of printing many years before, but it was not available to Europeans. Other epoch-making accomplishments during this age were the introduction of gunpowder, the discovery of the southeast passage by Vasco da Gama, Magellan's circumnavigation of the globe, heliocentric astronomy by Copernicus, the migration of Byzantine scholars to Europe after the fall of Constantinople in 1453, and the separation of church and state.

There were many great man in medicine during this period. We can mention only some of the more outstanding. Paracelsus (1493-1541) (*whose real name was Aureolus Theophrastus Bombastus von Hohenheim*) lived in Switzerland most of his life and was far in advance of his time, discarding Galenism and the Four Humors (blood, phlegm, yellow bile, and black bile). He advocated cleanliness in surgery and fought for the unity of medicine and surgery. He taught one principle that we teach *today—it is the guiding philosophy of surgical treatment*—". . . by their nature the tissues contain an inborn balsam that heals wounds. So should every surgeon know that it is not he, but nature that heals wounds."

In his day surgeons *cauterized wounds with hot irons, thereby retarding* healing. It has only been a short time since it was deemed necessary to change all surgical dressings daily. *Now a surgical wound is unmolested* for seven to ten days after a "clean" operation unless there is pain, fever, or inordinate drainage. Observe an injured dog. He lies with the injury exposed to the air and sun and keeps it moist by frequent licking. Such wounds are rarely infected, having healthy granulations, and heal with small amounts of scar tissue.

We are just coming through the *age of antiseptics*. It was once thought that the stronger antiseptics were best. Then different-colored dyes were employed. An attempt will be made to show in this book that antiseptics have a place but are not as *important* as was formerly thought. The emphasis today is on providing conditions which will help the body and its cells (nature) to annihilate the invading organisms, and it is now believed that in most instances some inert, soothing substance such as

physiological saline is preferable. *For any antiseptic that is strong enough to kill bacteria is strong enough to kill cells, and healthy cells are more important than temporary sterilization.*

Leonardo da Vinci (1452-1519), the artist who painted the Mona Lisa, drew excellent anatomic charts.

Andreas Vesalius (1514-1564) was one of the pioneer anatomists. He was one of the first to take the time to dissect the human body. This he had to do in his own room and then it had to be done so surreptitiously that no one would discover it.

Ambrose Paré (1510-1590) popularized anatomy by writing in the vernacular. He is the man who reintroduced the ligature for the control of hemorrhage. The story is told that at the Battle of Metz one of the soldiers had his arm shot off. It was the custom at camp to use boiling oil or hot irons for cauterization (comparable to strong antiseptics today) but neither was available. To arrest the hemorrhage, Paré tied the bleeding vessels and nothing more. The man recovered. The second great maxim in surgery which in one sense corresponds with that of Paracelsus is one by Paré: *"Je le pansay; Dieu le gaurit"*—"I dressed his wounds; God cured him." The new surgeon just out of school does not believe this; but as his experience accumulates and wisdom supplants incomplete knowledge, he will not only admit its truth but will scientifically interpret it (see Chapters 3 and 10).

Girolamo Fracastorius (1484-1553) wrote a poem about a shepherd who had blasphemed the Lord and contracted the "big pox." He named the shepherd Syphilis, from Ovid's story of the son of Mobe. Mobe's second son was named Sipylus.

The Seventeenth Century has been called the age of individual scientific endeavor.

This is the age of Shakespeare, Milton, Cervantes, Velasquez, Rembrandt; the composers and musicians, Bach of Germany and Purcell of England; Molière, the dramatist, and Descartes, the philosopher and physiologist, of France, Leibnitz, Newton, Sir Thomas Moore; Sir Walter Raleigh; Bacon, Locke, and Spinoza; the Thirty Years' War; The Spanish Armada; and the Great Rebellion of 1643.

William Harvey (1578-1657), the great comparative anatomist, described the circulation of the blood in his paper "De motu Cordis." Before the time of William Harvey this was not definitely known. Harvey knew how the blood got down the arteries and back through the veins, but he did not know how it crossed from the former to the latter.

Athanasius Kirchner (1602-1680) and *Anthony van Leeuwenhoek* (1632-1723) discovered the microscope. The former described protozoa (contagium vivum); the latter saw the capillaries. This was a forward step toward the understanding of the circulation and proved that William Harvey was correct in his beliefs.

R. Lower is credited with the first transfusion of alien blood (1665). A. Coga also recorded this procedure in 1667. Transfusion is mentioned in Pepys' diary (Nov. 14, 1666).

John Hunter (1728-1793) lived in the *Eighteenth Cenury.*

In the eighteenth century such names as Kant, Rousseau, Voltaire and Hume and Pope stand out in literature; in music, Mozart, Haydn and Gluck, and Handel; in chemistry and physics, Lagrange, Laplace, Cavendish, Priestly, Lavoisier, Galvani, Volta, Franklin, Fahrenheit; in medicine, Edward Jenner (1708-1777), great physiologist. In America it is the age of Fulton and Stephenson and of the Declaration of Independence by our illustrious statesmen.

Had we visited London before World War II we could have seen in the museum of the Royal College of Surgeons a complete collection of most of his specimens. He died a poor man. His living room, bathroom, and yard were full of animals. He did not publish one-half of what he accomplished. Among many other experiments he ligatured the external carotid artery on one side of a deer. The antler did not become necrotic and break off. He reasoned that blood must be getting to it in spite of the ligature. By this experiment he discovered what we know today as collateral circulation, a phenomenon which usually makes it possible for the surgeon to tie an artery without causing gangrene. (See Chapter 17.) He described a method for curing aneurysms and one for repair of tendons. He inoculated himself with gonorrhea pus and then delayed treatment to study the disease. A chancre developed. Unfortunately, the patient from whom the pus was obtained had both gonorrhea and syphilis. Consequently Hunter confused the two. He also described shock, phlebitis, pyemia, intussusception, inflammation, and the care of gunshot wounds; in addition, he delved into the field of dentistry, naming the teeth and using human teeth for artificial dentures. He is undoubtedly one of the greatest comparative anatomists and surgeons that ever lived.

In the *Nineteenth Century Rudolph Virchow* (1821-1902), a great pathologist, taught that "all cells come from other cells *(omnis cellula e cellula).* Prior to his time men spoke of spontaneous generation. Our entire body is simply a mass of cells and they all come from one cell, the ovum. The fertilization and development of this cell give rise to all other cells in the body. Later they developed into organs and tissues, such as liver, kidney, skin, etc., which have separate characteristics and functions, but if we know cells, we know the unit from which the entire human being is constructed. That is why it is necessary for us to study histology and cellular pathology. *The reaction of the body as a whole depends upon the changes which may occur in the cell.*

Louis Pasteur (1822-1895), the diminutive French chemist, indirectly did more to make modern surgery possible than any one man. He discovered that living organisms cause putrefaction and proved the theory of "spontaneous generation" to be a myth. He made a very important statement that to us seems obvious—he said in effect that the germ had a

parent from which it came. His biography should be read by everyone in medicine. He was not a physician, but his careful analytical mind led him into paths that transformed the concept of medical practice. Besides determining that "sour" or spoiled wine was due to living organisms, he showed how heat and then cooling would kill these bacteria (pasteurization). He also introduced vaccine for anthrax and the method of immunization for rabies which is in use today.

Robert Koch (1843-1895) is regarded as the father of modern bacteriology. Pasteur evolved the theory and Koch discovered bacteria and practically developed the science of bacteriology. Prior to his time no methods of staining were available by which bacteria could be easily identified. He also taught us how to grow bacteria on solid media. His description and identification of the tubercle bacillus was epoch-making.

His five postulates proving that a given organism was the cause of a given disease were: (1) The microorganism must be present and demonstrable in every case of the disease; (2) it must be isolated in a pure culture; (3) inoculation from such culture must reproduce the disease in susceptible animals; (4) it must be reobtained from the animals; (5) and it must be grown again in a pure culture.

Koch thought that a vaccine could be made which would immunize an individual against the germ in every instance. He is reported to have said that an individual is more or less the victim of any bacteria he might encounter. Needless to say, in these latter concepts he erred, as Ehrlich and Metchnikoff subsequently showed by their studies in immunity.

A contemporary of Pasteur's and Koch's was the Englishman, *Joseph Lister* (1827-1912). *Compound fractures were almost 90 per cent fatal* in his time; today the mortality is extremely low. By using carbolic acid as an antiseptic he cut down the mortality in England from 95 to 40 per cent. He correctly predicted that the time would come when the mortality from compound fractures would be almost nil.

Nurses in that day would spray carbolic acid over the patient, the surgeon, and the room. Instruments were soaked in it. That was antiseptic surgery. Often a member of the staff or the surgeon would be overcome from carbolic acid poisoning during the course of the operation. Here we have an example of the slow and halting but persistent progress of medicine. First, as a result of Pasteur's and Koch's discoveries, bacteria were found to be the cause of suppuration in wounds; then Lister decided that he must kill these bacteria in order to get healing with a minimum of infection; then Halsted and others reasoned that it would be far better to exclude them as much as posible and thus today we have substituted so-called aseptic for antiseptic surgery.

Strictly speaking, modern surgery is not aseptic. Even after the most meticulous scrubbing and use of antiseptics the skin still harbors bacteria in the sebaceous glands and hair follicles. Only the "transient" bacteria have been removed. Furthermore, there are more bacteria in a surgical wound toward the end of an operation. These enter from the air and from the nose and the throat of the surgeons and nurses in

R. Lower is credited with the first transfusion of alien blood (1665). A. Coga also recorded this procedure in 1667. Transfusion is mentioned in Pepys' *diary (Nov. 14, 1666)*.

John Hunter (1728-1793) lived in the *Eighteenth Cenury.*

In the eighteenth century such names as Kant, Rousseau, Voltaire and Hume and Pope stand out in literature; in music, Mozart, Haydn and Gluck, and Handel; in chemistry and physics, Lagrange, Laplace, Cavendish, Priestly, Lavoisier, Galvani, Volta, Franklin, Fahrenheit; in medicine, Edward Jenner (1708-1777), great physiologist. In America it is the age of Fulton and Stephenson and of the Declaration of Independence by our illustrious statesmen.

Had we visited London before World War II we could have seen in the museum of the Royal College of Surgeons a complete collection of most of his specimens. He died a poor man. His living room, bathroom, and yard were full of animals. He did not publish one-half of what he accomplished. *Among many other experiments he ligatured the external* carotid artery on one side of a deer. The antler did not become necrotic and break off. He reasoned that blood must be getting to it in spite of the ligature. By this experiment he discovered what we know today as collateral circulation, a phenomenon which usually makes it possible for the surgeon to tie an artery without causing gangrene. (See Chapter 17.) He described a method for curing aneurysms and one for repair of tendons. He inoculated himself with gonorrhea pus and then delayed treatment to study the disease. A chancre developed. Unfortunately, the patient from whom the pus was obtained had both gonorrhea and syphilis. Consequently Hunter confused the two. He also described shock, phlebitis, pyemia, intussusception, inflammation, and the care of gunshot wounds; in addition, he delved into the field of dentistry, naming the *teeth and using human teeth for artificial dentures. He is undoubtedly* one of the greatest comparative anatomists and surgeons that ever lived.

In the *Nineteenth Century Rudolph Virchow (1821-1902)*, a great pathologist, taught that "all cells come from other cells *(omnis cellula e cellula)*. Prior to his time men spoke of spontaneous generation. Our *entire body is simply a mass of cells and they all* come from one cell, the ovum. The fertilization and development of this cell give rise to all other cells in the body. Later they developed into organs and tissues, such as liver, kidney, skin, etc., which have separate characteristics *and functions, but* if we know cells, we know the unit from which the entire human being is constructed. That is why it is necessary for us to study histology and cellular pathology. *The reaction of the body as a whole depends upon the changes which may occur in the cell.*

Louis Pasteur (1822-1895), the diminutive French chemist, indirectly did more to make modern surgery possible than any one man. He discovered that living organisms cause putrefaction and proved the theory of "spontaneous generation" *to be a myth. He made a very important* statement that to us seems obvious—he said in effect that the germ had a

parent from which it came. His biography should be read by everyone in medicine. He was not a physician, but his careful analytical mind led him into paths that transformed the concept of medical practice. Besides determining that "sour" or spoiled wine was due to living organisms, he showed how heat and then cooling would kill these bacteria (pasteurization). He also introduced vaccine for anthrax and the method of immunization for rabies which is in use today.

Robert Koch (1843-1895) is regarded as the father of modern bacteriology. Pasteur evolved the theory and Koch discovered bacteria and practically developed the science of bacteriology. Prior to his time no methods of staining were available by which bacteria could be easily identified. He also taught us how to grow bacteria on solid media. His description and identification of the tubercle bacillus was epoch-making.

His five postulates proving that a given organism was the cause of a given disease were: (1) The microorganism must be present and demonstrable in every case of the disease; (2) it must be isolated in a pure culture; (3) inoculation from such culture must reproduce the disease in susceptible animals; (4) it must be reobtained from the animals; (5) and it must be grown again in a pure culture.

Koch thought that a vaccine could be made which would immunize an individual against the germ in every instance. He is reported to have said that an individual is more or less the victim of any bacteria he might encounter. Needless to say, in these latter concepts he erred, as Ehrlich and Metchnikoff subsequently showed by their studies in immunity.

A contemporary of Pasteur's and Koch's was the Englishman, *Joseph Lister* (1827-1912). Compound fractures were almost 90 per cent fatal in his time; today the mortality is extremely low. By using carbolic acid as an antiseptic he cut down the mortality in England from 95 to 40 per cent. He correctly predicted that the time would come when the mortality from compound fractures would be almost nil.

Nurses in that day would spray carbolic acid over the patient, the surgeon, and the room. Instruments were soaked in it. That was antiseptic surgery. Often a member of the staff or the surgeon would be overcome from carbolic acid poisoning during the course of the operation. Here we have an example of the slow and halting but persistent progress of medicine. First, as a result of Pasteur's and Koch's discoveries, bacteria were found to be the cause of suppuration in wounds; then Lister decided that he must kill these bacteria in order to get healing with a minimum of infection; then Halsted and others reasoned that it would be far better to exclude them as much as posible and thus today we have substituted so-called aseptic for antiseptic surgery.

Strictly speaking, modern surgery is not aseptic. Even after the most meticulous scrubbing and use of antiseptics the skin still harbors bacteria in the sebaceous glands and hair follicles. Only the "transient" bacteria have been removed. Furthermore, there are more bacteria in a surgical wound toward the end of an operation. These enter from the air and from the nose and the throat of the surgeons and nurses in

spite of careful masking. Experiments show also that there are more bacteria on the surgeon's hands at the conclusion of an operation than at the beginning. These facts have led to sterilization of the air in the operating room by ultraviolet light, scrubbing or débridement of the surgical wound at the conclusion of an operation, improved masks, and change of gloves (with second scrubbing) before the surgical closure.

Aseptic surgery with the aid of anesthesia (Crawford Long, 1815-1878, and Horace Wells, 1815-1848) has made modern surgery possible.

Crawford Long used ether in 1842 but he did not publish his work. Horace Wells, a dentist, used nitrous oxide in 1844. It was William T. G. Morton who persuaded John Collins Warren to try ether as an anesthetic agent on a patient with a vascular tumor just below the left jaw. This operation was successfully performed on Oct. 16, 1846.

Soporifics as a substitute for anesthesia were known to the ancients. Garrison quotes the Bible (Genesis 2:21), "And the Lord God caused a deep sleep to fall upon Adam and he slept: and he took one of his ribs, and closed up the flesh instead thereof." Opium, Indiana hemp *(Canabis indica)*, the mandrake *(Atropa mandragora)*, henbane *(hyoscyamus)*, dewtry *(Datura stramonium)*, hemlock *(Conium)*, and lettuce *(Lactuca)* were known to the Orientals and the Greeks. As early as the thirteenth century a mixture of drugs was recommended for surgical anesthesia. Man has always looked upon hell as a place of painful torture. Nothing imaginable could be worse than pain. The relief of pain has always been one of the first duties of the physician.

The *Twentieth Century* stands for preventive medicine: "Prevention is better than the cure." Today the "experimenters" (those materialists of old who wanted to reduce everything to chemistry and physics) and the clinicians (vitalists of old who leaned more toward constitutional factors) are working together for the onward progress of medicine. In surgery the more scientific the interpretation of a patient's ability to stand an operation, the less will be the necessity for invoking ill-defined constitutional factors.

MODERN SURGERY

Surgery is the treatment of malformations and disease by manual operation. It is perhaps the most important form of therapy. The surgeon must know medicine and must have manual dexterity. However, the surgeon's care does not always involve the use of the scalpel. There are times in surgical conditions when palliative measures are preferable. Corrective appliances in the care of fractures, hot fomentations in streptococcus cellulitis, drugs such as the sulfonamides, penicillin, and streptomycin, thermal and electrical agents—these belong to surgery also. Surgical operations are perhaps the most important part of surgery.

Today surgery has been divided into many different branches—orthopedic surgery, gynecology, ophthalmology, otolaryngology, traumatic surgery, neurosurgery, genitourinary surgery, etc. If we divide and subdivide the branches too much we may lose the proper perspective and arrive at the stage where "we can't see the forest because of the trees." It is well to remember that although surgery is chiefly a method

of treatment, its study includes the cause of disease (etiology), its morbid effects (pathology), and its symptoms and signs, making diagnosis and prognosis possible. It seeks to correct malformations, remove diseased tissue and foreign bodies, restore function, relieve pain, effect drainage for abnormal exudates, improve appearance; in short, it tries to restore a sick body to a normal state, as does all medical treatment. It is perhaps the "chief therapeutic resource of the physician."

A few surgical maxims that we have given medical students will summarize so-called modern trends of surgery. As the "principles" are studied, their true meaning will become apparent.

1. "A good surgeon is an internist who performs operations."

2. The more mature and accurate the diagnosis, the less a surgeon will have to explore. Therefore, careful medical and surgical diagnosis is essential.

3. Checking the surgeon to determine his speed used to be a habit among surgeons. More important is how cautious and how carefully the surgeon work—not how "fast" he is. A slow, careful operation is less apt to cause shock than one which is hurriedly and ruthlessly done in a few minutes.

4. Handle the tissues with loving kindness and they will heal in the same manner. This is a good maxim and is as important as asepsis in surgery.

5. The operative risk may be reduced by performing an operation in two or three stages if necessary.

6. There is no operation which has merit enough to be used on the patient who cannot stand it.

7. The greater the indications for surgery, the better the results.

8. Obese patients should not be subjected to abdominal operations (except in emergencies) until they have reduced.

9. Nature "in the raw" is not pleasing to our ethical or esthetic sense. However, a careful study of the manner in which animals care for their wounds may teach the surgeon that his chief function is to learn the methods of nature as best he can and to help rather than hinder her efforts.

10. When not to operate upon a patient is as important to know as when to intervene.

11. Cautiousness is the byword of the surgeon.

12. All operations may be dangerous to life and may be followed by distressing aftereffects.

13. Operations are to be avoided in hysterical or mentally deranged persons except when absolutely necessary.

14. The surgeon must never minimize the dangers of surgery; he should not "sell" an operation to a patient, and he must not promise that which is impossible or at most improbable.

15. The modern trend of surgery is toward conservatism.

16. Functional disease is made worse by calling a patient's attention to it.

17. The tacit or implied request of a patient on the operating table is: "My life is in your hands—be cautious; use all the skill, knowledge, and acumen you possess to cure me if possible and give me back to my loved ones."

The student will do well to learn the basic principles thoroughly; then these may be applied to any branch. They form the broad foundation upon which any superstructure may be built. This book is written with this thought in mind.

METHODS OF MODERN SURGERY

Preoperative Preparation.—The surgical operation really begins in the preparation of the patient for an ordeal. It is the surgeon's duty to evaluate the risk of the operation and to determine whether or not the patient is equal to it. He is pitting his skill, knowledge, and the operation against the ravages of the disease and the patient's ability to stand the surgery. Accurate diagnosis of the lesion to be attacked and of the patient's condition as a whole is necessary. Special states such as diabetes, dehydration, anemia due to blood loss, *alkalosis, acidosis, cardiovascular* renal disease, liver damage, and avitaminosis demand attention.

The Operation.—In performing the surgical operation the surgeon must be able to recognize diseased tissues by sight and touch; he must understand repair, the effects of bacterial invasion, the devastating effects of new growth and their method of dissemination. Moreover, in his efforts to remove diseased tissue, he must not lose sight of the patient's ability to withstand extensive procedure.

Thorough study and preparation of the patient and extreme care in the conduct of the operation will usually prevent untoward effects from the operation itself.

Postoperative Care.—This includes a continuance of measures instituted preoperatively and requires of the surgeon an intimate knowledge of wound healing, the effects of hemorrhage and shock, anoxemia, acido*sis, alkalosis, water balance, salt and protein metabolism, measures to* prevent thrombosis and embolism, urinary infections and lung complications, perversions in motor activity of the gastrointestinal tract, and the causes of postoperative fever. *A consideration of these entities will be* found in this book.

In the early years of surgery mortality was the surgeon's chief concern. Today a minimum mortality is taken for granted and the surgeon looks not only to the immediate recovery of the patient, but to his permanent cure as well. By a follow-up system he is able to evaluate the merits of his work.

A careful study of the natural course of a disease is important in evaluating the *efficacy of surgical treatment.* Perhaps nature can do more than the surgeon.

The surgeon, like the physician, has as his chief function, then, the saving of life and the restoration of health. To accomplish this he must have *surgical judgment.* This is based upon an accurate knowledge of surgical pathology and the fundamental principles of surgery.

The following is an outline of some of the more important considerations in operative surgery:

A surgical operation is an experiment in which the knowledge and skill of the physician is pitted *against the ravages* of the disease. It is his duty to evaluate the

patient's ability to stand surgery and to prepare him for the ordeal. He must be meticulous in the conduct of his operation and then meet the requirements necessary to assure recovery after the operation is over.

Aphorism—There is no operation that has merit enough to be used on a patient who cannot stand it

Preparation for Surgery—Preoperative Care

A. General considerations

Aphorism—Surgery demands careful attention to details

1. How does the patient vary from the normal
   a. Due to his disease
   b. *Due to his deficiencies caused by (1) the disease and (2) complications*
      If the patient is absolutely normal, very little preparation is necessary; if greatly abnormal, much treatment will be required
2. What are normals
   a. The ability to inhale and utilize oxygen
      Types of anoxia:
      (1) anoxic
      (2) anemic
      (3) stagnant
      (4) histotoxic
      (5) combinations
   b. The ability to make blood, retain it, and maintain an adequate circulation
      Causes of blood deficiency and circulatory failure:
      (1) Disease of the blood forming organs
      (2) excessive loss of blood
      (3) the disproportion between volume of circulating blood and vascular bed
   c. The ability to eat and drink and assimilate food and water
      The body contains 70 per cent of water: 50 per cent intracellular, 15 per cent intercellular, and 5 per cent intravascular; the labile portion is the intercellular component
      (1) The amount of water depends on the amount of sodium
      (2) The amount of sodium is always in isotonic concentration with the amount of potassium in the cells
      (3) The cell membranes are impermeable to cations but not to anions
      (4) There is a free interchange of electrolytes between the vascular tree and intercellular spaces

Aphorism—The alimentary canal and not the veins were made for eating and drinking; underhydration is better than overhydration

   d. *The ability to eliminate waste products through kidneys,* bowels, and lungs and thus maintain a normal acid base balance
      Acid base balance is important and closely related to water balance
      (1) the only base is that which is ingested
      (2) acids are constantly being formed by the body
      (3) the control of this balance is related to two factors:
         (a) chemical, which are the buffers of the blood

(b) physiological, which are the means of eliminating excessive amounts of acids or base by the lungs or kidneys; fluids and chemicals are used in an effort to keep the balance as nearly normal as possible.

Aphorism—Acidosis is better than alkalosis

e. The ability to withstand infection by healthy antibody system

(1) the age of antiseptics is gone

(2) chemotherapeutic agents act by making the environment unfavorable for bacterial growth

(3) Antibiotics interfere with reproduction of bacteria

(4) No therapeutic agent cures infection; this is accomplished by healthy, active cells and antibodies

f. The ability to withstand the nervous strain of anesthesia and surgery

Barbiturates should be used with great caution

(1) They are respiratory depressants and many individuals are sensitive to them

(2) Morphine in small doses with atropin is still an excellent combination

(3) Demerol is useful in chest surgery because it is less depressive to the respiratory center

Conduct of Operation

A. Anesthetic

1. Oxygen requirement met by
   a. Open airway
   b. Endotracheal tube in chest surgery especially
   c. Oxygen administration
   d. Automatic respiration
   e. Elimination of carbon dioxide

B. Fluids needed, depending on

1. Degree of subhydration prior to surgery
2. Amount of sweating and length of operation to make up insensible water loss

C. The amount of blood lost in surgery is difficult to estimate; many methods are in use

1. The use of dry sponges and weighing them
2. Colorimeter
3. Standard scales of blood loss for various operations
4. Hematocrit, hemoglobin, red blood count, and plasma protein determinations are useless because hemodilution does not occur until two hours or more after the blood has been lost
5. Best guide is blood pressure and pulse rate together with a knowledge of approximate amount of blood lost in any particular operation

Postoperative Care

How has the operation affected the condition of the patient? If not at all, relieve pain and nothing more.

Aphorism—Excessive treatment is an unnecessary burden to patient and may have serious consequences

Consider:

1. Interference with oxygen consumption and utilization
2. Loss of blood and fluid

3. Contamination which may lead to infection
4. Ability to eat and drink and assimilate food and water
5. Ability to eliminate water through kidneys; Anuria: prerenal, renal, and postrenal
6. Pain and nervous strain
7. Enervating effects of prolonged bed rest and possible complications (thromboembolism, lung complications, bladder complications, bowel distention) are, to a large extent, obviated by early mobilization

Chapter 2

PATHOLOGY

Pathology is the study of disease, its causes, manifestations, and effects. It is always changing, always new. Although it deals chiefly with morphological changes, it is inextricably linked with altered physiological processes. The modern clinical pathologist is a consultant who helps in the diagnosis and treatment of disease.

A study of the normal (anatomy and histology) must precede the study of the abnormal (pathology). By careful examination of the patient an attempt is made to diagnose his ailment, and then if an operation is performed or if tissue is removed for biopsy, it must be carefully examined. In this way we learn how to interpret clinical symptoms and signs in the light of pathological changes.

Gross Pathology.—Gross pathology is studied at the (1) surgical table and at (2) autopsy.

Medical students must witness and perform many autopsies, because here the effects of disease are best learned. The surgeon must observe and handle diseased tissue so that he may recognize with his hands as well as his eyes the gross characteristics of disease.

Microscopic Examination.—Lesions may be studied in sections of tissue from (1) autopsy, (2) surgery (frozen section and paraffin sections of tissue and organs removed), (3) biopsy, and (4) living tissue—vital and supravital staining.

Frozen Section.—The microscope is indispensable for detailed study. Very often the surgeon performs an operation on a patient with a new growth and he cannot be sure from gross appearance whether it is a malignant or benign neoplasm. The pathologist makes a frozen section and examines the growth under the microscope. In fifteen or twenty minutes he can usually tell whether it is a malignant lesion which requires radical and extensive surgery or a benign growth for which local excision will suffice. Many of the more common neoplasms will be discussed later in our text. We shall also consider the history and findings in the case and thus reconstruct the entire clinical as well as pathological picture.

Biopsy.—A patient may have a swelling which may be a cyst or an enlarged lymph gland or an infectious process. The diagnosis may be extremely difficult. The surgeon may remove the lymph gland or edge of the ulcer and submit it to the pathologist and a diagnosis may be made in this way. This is known as surgical biopsy. The term implies both the removal and examination of the tissue. Another form is the needle biopsy; some cells from the diseased tissue are aspirated into a

hollow needle after making a small incision. The specimen is then spread on a slide and studied under the microscope. This is especially helpful in the diagnosis of brain tumors.

Vital Staining.—A small incision is made over the sternum. A large needle and syringe are used to aspirate some bone marrow for study. This procedure is employed in the diagnosis of anemias and leucemias. Some fatal cells are not seen normally after birth; other cells are found only in bone marrow. In blood dyscrasias marrow cells may be found in the circulating blood and very primitive cells in the marrow.

Supravital staining has to do chiefly with certain "reticulated" red corpuscles, which contain a coarse skein or network of granular filaments. This is an attempt to stain the blood cells in the living state by the administration of certain dyes.

***Examination of Microorganisms and Cells Causing or Complicating* Disease.**—

Exudates (Pus or Serum).—Exudates are composed of the fluid and cellular parts of the blood and tissues and occur as a result of active hyperemia in response to an injury (bacterial, mechanical, or chemical). This implies that insofar as blood constituents are concerned they have been permitted to leave the capillaries as a result of increased permeability. Transudates are composed of the fluid parts of the blood with some cells. They traverse normal capillaries and vary in amounts and consistency in different parts of the body, depending upon slight variations in capillary permeability. Although not produced by active hyperemia, they are nevertheless affected by the hydrostatic and osmotic pressures which prevail. If, however, as a result of anoxemia, capillary walls become affected, transuding fluid becomes an exudate. Based upon this definition, ascites and edema of the extremity due to occluded veins or lymphatics would be classed as exudates, whereas edema due to hypoproteinemia as seen in nephrosis or starvation states would be called transudates.

Smears are usually made by dipping an applicator with cotton into the exudate and then lightly stroking a glass slide; for example, a smear from the throat to determine whether or not diphtheria is present, or from the urethra for gonorrhea. These same exudates may be cultured in test tubes to see if the bacteria will grow so that they may be definitely identified. Recently tryspin has been used to digest the material so that the tubercle bacillus may be more easily stained and identified. If in extreme doubt, some of the material from the lung or pleural cavity, for example, is injected into a guinea pig, an animal that is extremely susceptible to tuberculosis. In about ten days if the fluid contains tubercle bacilli the guinea pig will die of tuberculosis, or it may be sacrificed sooner and show tuberculosis at autopsy. In suspected carcinoma deciduous cells are sought by centrifuging the exudate and staining the smear.

Blood and the Other Body Fluids.—If a patient l for example, blood smears may show the presence of site. From the same patient a blood culture may be n withdrawn and incubated on different media; if it show bacterium may be identified. This is especially imp fever and also in undulant fever, where we depend alm blood culture and agglutination tests for diagnosis.

The examination of urine and stool cultures in pat rhea is important. This is especially true in typhoid fe amoebic dysentery (stool), for parasites and ova. Carc also searched for in suspected cases. This is especially tr of the kidney or bladder (urine cells).

Serology.—Wassermann, Kahn, Kline, or Mazzini b *syphilis should be routine. Often it is necessary to make th* on the blood and spinal fluid.

Colloidal gold curve is of aid in the diagnosis of pares cerebrospinal diseases.

Allergic phenomena. Certain allergic states, such as hay fever, defy successful cure unless the causative agent is by skin tests.

Chemical Examination of Blood, Urine, Feces, Gastric Ju

Blood.—The calcium content of the blood is important in roidism, the carbon dioxide combining power in acidosis and oxygen determination in anoxemic states and arteriovenous nonprotein nitrogen and uric acid in azotemic states produced by tis, etc., blood sugar in diabetes, and serum globulin and alb edema.

Urine.—Abnormal constituents are sugar, acetone, and diacet in diabetes, albumin in nephrosis, bile in obstructive jaundice, etc.

The *Friedman* test for pregnancy is done by the injection of t tient's urine into an immature female rabbit's ear; the animal is sacrificed and the tubes and ovaries are examined for maturation o follicles. The *Aschheim-Zondek* test, which was the original test for p nancy, is now used for the quantitative determination of the gonadotr hormone. Immature female mice are used and the results expressed mouse units per liter.

Feces.—Tests for blood, occult blood (blood that is not visible to the naked eye), undigested fats, etc., are available.

Gastric juice may be tested for the amount of free hydrochloric ac and combined acid. This is a great aid in the diagnosis and treatment of peptic ulcer (high acid) and pernicious anemia (achlorhydria).

Cytologic Examinations.—

Blood.—Leucocyte, erythrocyte, and Schilling counts and various specific cells are listed on the laboratory sheets. Normally, immature

polymorphonuclear leucocytes make up about 10 per cent of the total differential count. In infections the blood sends out the white cells in great numbers. Schilling counts record the number of immature cells (band cells, myelocytes, and metamyelocytes); if these are present in large number, 20 to 30 per cent, a "shift to the left" is said to have occurred. This is seen in acute sepsis, appendicitis, etc., and implies that the body is not keeping pace with the infection and is sending out untrained "soldiers." A "shift to the right" means that the blood is fighting with its adult white cells and is combating infection successfully.

If the blood count showed 80,000 white cells, the surgeon would think of leucemia rather than infection although pertussis in infants may produce extreme leucocytosis (mostly lymphocytes). Therefore, cell counts are done routinely on all patients who enter the hospital. The significance of this will be more apparent when the subject of infection is discussed in Chapters 3 and 4. Thrombocytes (blood platelets) are counted in all hemorrhagic states. This test is used in the diagnosis of thrombocytopenic purpura.

Cytologic examination of *pus* and other *exudates* is important to the surgeon because it tells him the type of infection he is dealing with. The serosanguineous exudate of the streptococcus and the thick creamy purulent exudate of staphylococcus are more or less characteristic. If he looks at fluid from the pleural cavity and it contains pus cells, it is probably an empyema; if it is clear except for a few lymphocytes, it probably is tuberculosis; if many red blood cells are found in the exudate, cancer of the lung may be present. Cancer cells may be found by centrifuging and making a "button" and then staining with hematoxylin and eosin stain; or a saturated aqueous solution of picric acid may be used, the tissue desquamations fixed in paraffin blocks, and then cut and stained with hematoxylin and eosin.

The Papanicolaou technique consists of placing the exudate on slides, immersing them in ether and 95 per cent alcohol (equal parts), leaving the slide in this mixture for one to twenty-four hours, depending on when the stains can be made, and then staining with the Papanicolaou polychrome stain. If the smear is to be sent away, the slide should be covered with glycerin.

Metabolism Tests.—Metabolism is a term used to include the different chemical processes which occur in the tissues. Growth and heat production depend on these processes, and energy for muscular activity and vital functions is derived from them.

The basal metabolic rate means the basal amount of energy that is used by the patient. Basal in the sense that the patient is at complete muscular and mental rest and in the postabsorptive state, twelve to fourteen hours after a meal when digestive processes are over. It is found by measuring oxygen consumption. The test properly done and interpreted is especially useful in the diagnosis and treatment of toxic goiter.

Blood and the Other Body Fluids.—If a patient has chills and fever, for example, blood smears may show the presence of the malaria parasite. From the same patient a blood culture may be necessary. Blood is withdrawn and incubated on different media; if it shows any growth, the bacterium may be identified. This is especially important in typhoid fever and also in undulant fever, where we depend almost entirely upon blood culture and agglutination tests for diagnosis.

The examination of urine and stool cultures in patients with diarrhea is important. This is especially true in typhoid fever (urine) and amoebic dysentery (stool), for parasites and ova. Carcinoma cells are also searched for in suspected cases. This is especially true in carcinoma of the kidney or bladder (urine cells).

Serology.—Wassermann, Kahn, Kline, or Mazzini blood tests for syphilis should be routine. Often it is necessary to make these tests both on the blood and spinal fluid.

Colloidal gold curve is of aid in the diagnosis of paresis and other cerebrospinal diseases.

Allergic phenomena. Certain allergic states, such as asthma and hay fever, defy successful cure unless the causative agent is determined by skin tests.

Chemical Examination of Blood, Urine, Feces, Gastric Juice, Etc.—

Blood.—The calcium content of the blood is important in parathyroidism, the carbon dioxide combining power in acidosis and alkalosis, oxygen determination in anoxemic states and arteriovenous fistulas, nonprotein nitrogen and uric acid in azotemic states produced by nephritis, etc., blood sugar in diabetes, and serum globulin and albumin in edema.

Urine.—Abnormal constituents are sugar, acetone, and diacetic acid in diabetes, albumin in nephrosis, bile in obstructive jaundice, etc.

The *Friedman* test for pregnancy is done by the injection of the patient's urine into an immature female rabbit's ear; the animal is later sacrificed and the tubes and ovaries are examined for maturation of the follicles. The *Aschheim-Zondek* test, which was the original test for pregnancy, is now used for the quantitative determination of the gonadotropic hormone. Immature female mice are used and the results expressed in mouse units per liter.

Feces.—Tests for blood, occult blood (blood that is not visible to the naked eye), undigested fats, etc., are available.

Gastric juice may be tested for the amount of free hydrochloric acid and combined acid. This is a great aid in the diagnosis and treatment of peptic ulcer (high acid) and pernicious anemia (achlorhydria).

Cytologic Examinations.—

Blood.—Leucocyte, erythrocyte, and Schilling counts and various specific cells are listed on the laboratory sheets. Normally, immature

Leucocytes

Men, 5,000 to 10,000 per cubic millimeter of blood

Women, 5,000 to 10,000 per cubic millimeter of blood

Differential count

	RELATIVE VALUES (%)	ABSOLUTE VALUES (PER C.MM. OF BLOOD)
Neutrophils	60-70	3,000-7,000
Basophils	0.5-1	0- 100
Eosinophils	1-3	50- 300
Immature cells		
Myelocytes	0	
Metamyelocytes	2-4	
Band cells	4-10	
Lymphocytes	20-40	1,000-4,000
Monocytes	2-6	100- 600

Color index, 1.0

Volume of packed cells (Wintrobe hematocrit method)

Men, 46 c.c. per 100 c.c. of blood

Women, 42 c.c. per 100 c.c. of blood

Average figure for both sexes, 42.4 per 100 c.c. of blood

Volume index, 1.0

Saturation index, about 1.0

Mean corpuscular hemoglobin, 27 to 32 micromicrograms

Mean corpuscular hemoglobin concentration, 32 to 38 per cent

Mean corpuscular volume, 80 to 94 cubic micra

Reticulocytes, 0.1 per cent of erythrocytes

Thrombocytes platelets

250,000 to 350,000 per cubic millimeter of blood

1 platelet for every 20 erythrocytes (Fonio's smear method)

Coagulation time

2 to 6 minutes (slide method)

3 to 8 minutes (capillary tube method)

5 to 10 minutes (Lee and White's method—venous blood in test tube method)

Bleeding time

2 to 3 minutes

Clot retraction time

Beginning retraction in 1 to 6 hours

Complete in 24 hours

Resistance of erythrocytes to hypotonic salt solutions (fragility test)

Beginning hemolysis from 0.44 to 0.42 per cent NaCl

Complete hemolysis from 0.34 to 0.42 per cent NaCl

Icterus index, 1 to 5

Van den Bergh reaction

Indirect reaction—Normal serum contains 0.1 to 0.3 mg. bilirubin per 100 c.c. of blood

Sedimentation rate

Men, 0 to 8 mm. in 1 hour

Women, 0 to 2– mm. in 1 hour

Sheep cell agglutination, not above 1.8 dilution

Experimental Pathology.—Occasionally we read of the activities of a strange organization called the antivivisection society. This group would prevent all vivisection. This attitude, if carried out, would delay the progress of medicine materially. Such diseases as cancer, heart disease, leucemias, endocrine dyscrasia, etc., must be conquered through experiments on lower animals.

This is the great uncharted and unknown field of pathology. Abnormal states are purposefully induced in animals so that they may be accurately studied as to their cause *and pathological changes in the hope* that successful treatment will follow. Such conditions as shock, burns, intestinal obstruction, peptic ulcer, lung abscess, empyema, etc., have been produced in experimental animals and, as a result, the treatment of *these conditions in the human being has been greatly improved.*

In summarizing the value of pathologic tests we may say that some of them are so important as to be routinely required (blood counts, urinalysis, and Kline and Mazzini tests); others are needed to help establish *the diagnosis, to guide in treatment, or to help in prognosis.* In a few instances they are diagnostic; in many they must be viewed in the same light as any other symptom.

Certain laboratory work is routine and indispensable. For example, a child comes to the hospital with suspected appendicitis. A routine blood count and urinalysis are done. This helps in diagnosis, prognosis, and treatment.

Routine urinalysis may reveal a pyelitis or diabetes which may simulate appendicitis. A concentrated urine with acetone indicates dehydration and acidosis which requires treatment before any operation can be performed. (See Chapters 11 and 12.)

Routine leucocyte counts may reveal an unsuspected leucemia. The acuteness of the infection (Schilling count) is revealed and a more accurate prognosis may be given (Walker index). (See Chapter 4.) A very high hemoglobin and red blood cell count *(hemoconcentration) indicates dehydration, showing that* a loss of plasma has occurred (due to starvation, vomiting, or diarrhea or diffuse inflammation of the peritoneum). (See Chapters 11 and 14.) This requires blood transfusion. Plasma proteins and hemoglobin and hematocrit values are important in the treatment of shock and dehydration. These may be determined quickly by the copper sulfate method for measuring specific gravities of whole blood and plasma.

In this way errors in diagnosis are minimized and proper preparation of the patient is possible before surgical intervention. This is more important in complicated appendicitis than the time of operation.

The *following is a list of normal values for laboratory determinations* which has been compiled from various sources and from experience with tests done at the Indiana University Medical Center.

Blood—Adults

Hemoglobin (Newcomer's method)

Men, 14.5 to 16.9 Gm. per 100 c.c. of blood
Women, 12.5 to 15.0 Gm. per 100 c.c. of blood

Erythrocytes

Men, 4.5 to 6.0 million per cubic millimeter of blood
Women, 4.0 to 5.6 million per cubic millimeter of blood

TABLE I

GROUP				SERUM	SERUM OF GROUP	RED BLOOD CORPUSCLES OF GROUP				PER CENT OF ADULTS IN EACH GROUP
LANDSTEINER	MOSS	JANSKY	CORPUSCLES			AB	A	B	O	
AB	I	IV	Agglutinogens AB	Agglutinin o	AB; that is, agglutinin o	–	–	–	–	7
A	II	II	Agglutinogen A	Agglutinin b	A; that is, agglutinin b	+	–	+	–	40
B	III	III	Agglutinogen B	Agglutinin a	B; that is, agglutinin a	+	+	–	–	10
O	IV	I	Agglutinogen O	Agglutinins ab	O; that is, agglutinin ab	+	+	+	–	43

+, Hemoagglutination; –, no hemoagglutination.

Blood Groups

Transfusion *reactions occur* because of hemolysis or agglutination of the donor's or recipient's cells or both. *Since hemolysis does* not occur without agglutination, the latter is observed in blood *matching. Two factors are involved in this* process: agglutinins in plasma and agglutinogens in cells.

Landsteiner's four basic groups *are based on two isoagglutinins* in serum, designated as a and b, and two isoagglutinogens *in cells, designated as A and B. In* Table I is a classification of the four blood groups of Landsteiner, *Moss, and Jansky* and their antigenic analyses.

It is apparent that group A agglutinogen could not harbor an agglutinin or its own cells would be agglutinated. Thus a person of group A has b agglutinins. Such an individual may receive the corpuscles of his own group or of group O. A person of group B may receive group B or group O blood, but one with group O blood may receive cells from only his own group. Persons of group AB may receive corpuscles from any group but may give only to their own group.

In transfusions the important fact to remember is that the donor's cells must not contain isoagglutinogens which will be agglutinated by the isoagglutinins of the recipient's serum. Since type O has no isoagglutinogens, persons of this type may be used as universal donors. Type O serum contains isoagglutinins ab which, when transfused into the recipient slowly, are not present in high enough titer to clump *the recipient's cells. Furthermore*, much of the serum so given is quickly lost. (See Chapter 13.) *Persons of type AB may be used as universal recipients since their serum contains no isoagglutinins. However, it is best that cells and sera be cross-matched* and that same types be used if possible. Many subgroups have been established (A_1 or A_2, A_1B or A_2B) which are not important in everyday practice. (For heredity of blood groups, see Chapter 10.) Infused erythrocytes survive almost as long as those made by the recipient provided there are no incompatabilities. Their ability to take on all functions of the recipient's erythrocytes is not fully understood.

Compatability tests are not required for plasma transfusions. Indeed many donors may be used, of different blood groups, for plasma powder. The dehydrated plasma is diluted to isotonicity with distilled water or distilled water and glucose or saline solutions and immediately used in the treatment of shock and hemorrhage (q.v.). Reactions are not uncommon from reconstituted plasma and the dangers of homologous serum jaundice which are present *in all transfusions are even more prevalent following the use of plasma powder obtained from various donors.*

An individual's serum *may agglutinate* its own corpuscles when the blood is *cooled. This is said to be due to cold autoagglutinins, not isoagglutinins. Agglutinogens* other than those mentioned include M and N factors. There are no normal isoagglutinins for them in human blood and therefore they are not important in ordinary typing. Fifty per cent of the white population are of type MN, 30 per cent are of type M, and 20 per cent are of type N. Tests for M and N agglutinogens may be useful in paternity disputes since they are dominant characteristics. Still other agglutinogens and agglutinins may be associated with liver damage *or may be bacterio*genic. Repeated transfusion from the same person *may cause reactions due to* agglutinogens in small *amounts which act as antigens, stimulating* the formation of agglutinins.

Rh Factor.—If red blood corpuscles of the *Macaca rhesus* monkeys are injected *into rabbits or guinea pigs,* agglutinins develop against them. These agglutinins will also agglutinate the blood of 85 per cent of human beings regardless of isoagglutinin groups. Fifteen per cent lack this agglutinogen which is responsible for the reaction and which has been termed the Rh factor. Many atypical reactions are probably due to transfusions given an Rh-negative person with agglutinins *for corpuscles containing* the Rh factor. These agglutinins arise usually under *the following conditions:* (1) Patients who have had one *or more previous transfusions* from the same group or universal donor group; (2) *first* transfusions in a pregnant woman or recently post-

cells are frequently encountered in the blood of infants and children. Cellular immaturity in the blood of children is not always considered of serious import but indicates an instability of the embryonic hematopoietic system.

Blood Chemical Constituents and Miscellaneous Data

Nonprotein nitrogen (Made of urea N, uric acid, creatinine, amino acid N, creatine, undetermined N), 25 to 40 mg. per 100 c.c. of blood

Urea nitrogen, 18 to 35 mg. per 100 c.c. of blood

Uric acid, 1 to 3 mg. per 100 c.c. of blood

Creatinine, 1 to 2 mg. per 100 c.c. of blood

Urea clearance, 80 to 120 per cent of accepted normal excretion

Sugar, 80 to 200 mg. per 100 c.c. of blood

Chlorides

Plasma, 570 to 600 mg. per 100 c.c.

Cells, 285 to 300 mg. per 100 c.c.

Calcium

9 to 11.5 per 100 c.c. in the plasma of adults

Slightly higher (10 to 12 mg. per 100 c.c.) in that of children

	PLASMA	WHOLE BLOOD	CELLS
Magnesium	2.7 mg. per 100 c.c.	4 mg.	6 mg.
Sodium	340 mg. per 100 c.c.	160 mg.	0
Potassium	18 to 22 mg. per 100 c.c.	200	420

Iodine, 1.001 mg. per 100 c.c. plasma

Serum protein—Total, 6 to 8 Gm. per cent

Albumin, 4.5 to 5.5 Gm. per cent

Globulin, 1.5 to 3.0 Gm. per cent

Fibrinogen, 0.27 Gm. per 100 c.c.

Albumin-globulin ratio, 1.5 to 3.5

Colloid osmotic pressure, 290 to 430 mm. H_2O

Specific pressure (pressure per gram per cent of protein), 15 to 54 mm. H_2O

Specific gravity is the ratio between the density of a body and the density of a standard substance, usually water.

Plasma specific gravity: 1.027

Whole blood specific gravity: 1.060

Blood viscosity is 5 to 6 times the viscosity of distilled water (distilled water as unit).

Plasma viscosity is 1.8 to 2.1 times the viscosity of distilled water.

Bromide

Less than 50 mg. per cent. Normally none is present. Less than 50 mg. is usually of no clinical significance during its administration.

Oxygen

Arterial, 15 to 20 volumes per cent

Venous, 10 to 18 volumes per cent

Free CO_2 is 1/20 of plasma bicarbonate or 2.5 to 3.5 volumes per cent

CO_2 combining power of the plasma

55 to 80 c.c. of carbon dioxide per 100 c.c. of plasma (venous); arterial, 45 to 55 per cent

In children, 40 to 55 c.c. of carbon dioxide per 100 c.c. of plasma (venous)

Blood diastase

70 to 200 mg. of sugar per 100 c.c. can be converted from starch

Cholesterol, 150 to 200 mg. per 100 c.c. of blood

partum mother. Here the mother is Rh negative but the fetus has corpuscles which are Rh positive inherited from his Rh-positive father. A mother's red blood corpuscles may have no Rh agglutinogen. Due to leakage of agglutinogens *from the fetal circulation into the mother's circulation, agglutinins may form* in the mother against the cells of the fetus. Also an Rh-negative mother may have one or more Rh-positive offspring without a state of isoimmunization. Since an Rh-negative female who is immunized remains potentially sensitized throughout life, it is *important to test all female patients* for the Rh factor. If they are *Rh negative, they should receive* Rh-negative blood. (3) *Rarely* reactions occur with a first transfusion although there is no history of previous sensitization by transfusion or pregnancy.

The importance of this factor in pregnancy is obvious. *The mother's agglutinins in her serum against the corpuscles of the* Rh-positive fetus may enter the fetal circulation, destroying the corpuscles of the child. This results in a hemolytic anemia known as erythroblastosis fetalis. There are three clinical types: (1) Hydrops fetalis, a rare form characterized by anasarca and enlargement of the liver, spleen, and heart; *the fetus is usually stillborn or dies shortly after birth.* (2) Icteris gravis neonatorum. There is an increasing jaundice with purpura. Recovery may occur. Normal human serum or whole blood was formerly given intramuscularly. Transfusions are better. Most observers believe that Rh-negative blood should be used because the fetus has agglutinins against Rh-positive blood. Small transfusions, *40 to 60 c.c., should be slowly administered. Another method of giving blood is replacement transfusions, using* the umbilical vein. *Long plastic cannulas* are employed and *30 c.c.* are given, *then 30* c.c. withdrawn, until the blood volume has been replaced (350-500 c.c.). Vitamin K is also given. (3) Hemolytic anemia of the newborn, which may occur without erythroblastemia and without hydrops or jaundice. The spleen is enlarged. Treatment is the same as for icteris gravis neonatorum. *Rh factor subgroups* consist of Rh_o, Rh′, Rh″. Eighty-five per cent of Caucasians possess the Rh_o factor along with one or both the others; *3½ per cent possess only one factor;* and 13 per cent lack all three factors (Rh negatives).

Blood—Children

Erythrocytes, leucocytes, platelets, and hemoglobin values are *high at birth.* The following normal values are given by Blackfan and associates for normal newborn infants:

Hemoglobin, 95 to 140 per cent
Erythrocytes, 5 to 8 million per cubic millimeter of blood
Leucocytes, 15,000 to 25,000 per cubic millimeter of blood
Platelets, 200,000 to 400,000 per cubic millimeter of blood

With the first three months there is a physiological decrease in red cells and hemoglobin (the latter frequently falling to a level of as low as 65 to 75 per cent) which is explained by Davidson and Leitch as the result of two factors:

1. A decrease in *bone marrow activity due to the high* oxygen tension of extrauterine life and
2. A destruction of erythrocytes by hemolysis. *The red cell and hemoglobin* values rise until the normal level is reached about the sixth month.

The differential count likewise is altered during infancy. There is a neutrophilia *immediately after* birth which gradually recedes to 25 to 50 per cent during the first *two weeks. Following* this period there is a gradual increase of 40 to 60 per cent during the next five or six months, but a normal level is not attained until about the twelfth year. This relative *decrease of neutrophils* between the second week and the twelfth year is accompanied *by a slight relative and* absolute lymphocytosis. Eosinophils, basophils, and monocytes *occur soon after birth in higher* numbers than in adults, but normal levels are usually reached *at the end of two weeks. Immature* red and white

Gastric Acidity

Free HCl 25 to 50 (25 to 50 c.c. N/10 HCl per 100 c.c. gastric juice)
Acid per cent
Total acidity, 50 to 75 acid per cent
Gastric mucin, 0.4 to 0.7 mg. per 1 c.c. of gastric juice

Basal Metabolic Rate

Plus 15 to minus 15

CLASSIFICATION OF DISEASE FROM THE STANDPOINT OF THE PATHOLOGIST

1. *Degenerative or involutional diseases*
   Examples: Arteriosclerosis, cataract, atrophies of organs, gangrene due to arteriosclerosis, fractures due to osteosclerosis, etc.
2. Congenital malformations and abnormalities
   Examples: Cleft palate, harelip, clubfoot, hernia, etc.
3. Trauma or affections caused by injurious contact between the body and its environment
   Examples: Burns, frostbite, fractures, wounds, poisonings, etc.
4. Deficiency diseases or absence of essential nutritional substances due to:
   a. Environment (starvation, wrong foods, lack of vitamins, etc.)
   b. *Inability to absorb food (gastric carcinoma, duodenal fistula, etc.)*
   c. Inability to metabolize (pernicious anemia, diabetes, etc.)
5. Disorders of metabolism
   Chemical processes take a perverted course or are incomplete
   Endocrine disorders such as diabetes, gout, obesity, hyperthyroidism, etc.
   Allergy
6. Neoplasms
7. Diseases caused by animal parasites
8. Diseases caused by living microorganisms
   Bacteria and fungi
9. Diseases caused by filtrable viruses
10. Obstruction to principal ducts or outlets of organs
    May result from diseases listed under numbers 2, 3, 6, 7, 8, and 10
    Intestinal, common bile duct, ureter, etc.

This list will undoubtedly be changed as new discoveries are made and a better understanding of diseases is evolved. The surgeon should have a general outline of disease which he may apply in a practical manner. Very often it will be difficult to categorize an illness without lab-

Cholesterol esters, 110 to 145 mg. per cent
- Lecithin, 200 to 250 mg. per cent
- Lipase, 0.2 to 1.5 c.c. N/20, Na OH for each cubic centimeter
- Lipids, 650 to 750 mg.

Phosphorus (inorganic)
- Adults, 2 to 5 mg. per cent
- Children, 4 to 7 mg. per cent

Phosphatase, 1.5 to 5 (Bodanski units)

Rose bengal test, 80 to 120 per cent of normal excretion

Bromsulphalein test
- At 5 minutes 20 to 50 per cent retention
- At 30 minutes, no retention
- Less than 15 per cent should be retained at the end of 1 hour

Blood volume, 90 c.c. per kilogram of body weight; *plasma volume*, 50 c.c. per kilogram of body weight

Blood *sulfanilamide*
- Should not exceed 10 mg. per cent while being administered

Blood sulfapyridine
- Should not exceed 8 to 12 mg. per cent while being administered

Sulfadiazine, 10 to 12 mg. per cent

Sulfathiazole, 5 to 8 mg. per cent

Thiocyanate, 6 to 10 mg. per cent

Blood ascorbic acid, 1.5 to 2.0 mg. per 100 c.c. of blood plasma

Prothrombin
- Expressed in per cent of normal control; about 35 mg. per 100 c.c. of whole blood
- Prothrombin levels below 50 per cent of normal may be accompanied by bleeding. This is seen in obstructive jaundice and cirrhosis of the liver. Although this is extremely variable and the bleeding tendency may not be present when only 20 per cent of normal is present, it may occur with prothrombin levels of 70 to 80 per cent of normal. This is explained by the small or large reserve of prothrombin which may be present. Vitamin K is not a part of the prothrombin molecule. It aids in its synthesis

Urine

P. S. P. test
- 15 minute specimen, 25 per cent or above
- 30 minute specimen, 15 to 20 per cent

Galactose tolerance test
- Patient should not excrete more than 1.5 Gm. in the five-hour period following ingestion

Urobilin, 0.5 to 2 mg.

Spinal Fluid

Spinal fluid sugar, 40 to 60 mg. per cent

Spinal fluid protein, 20 to 40 mg. per cent

Colloidal gold curve
- Normal, 0000000000
- Meningovascular neurosyphilis, 0244310000
- Paresis, 5554321000
- Brain tumor and tuberculous meningitis, 0000123100
- Meningitis other than tuberculous, 0000012334

oratory aid. Sometimes even then such classification may be untenable. In general, the following guide may be used:

1. That with which the individual is born (congenital malformations)
2. That which he naturally develops as he declines (degenerative or involutional diseases)
3. That which has to do with perverse functional activities of the body
   a. Chemical—secretions and excretions abnormal in amount or kind
   b. Mechanical activity—abnormal in amount or action
   c. Disorders of metabolism
4. That which is caused by injurious contact with his environment
   a. Physical and psychic
   b. Germs and animal parasites
   c. Food
      Too much
      Too little (starvation states)
      Improper kind (vitamin deficiencies)
5. Circulatory disturbances
6. Neoplasms

The treatment of disease may be outlined as follows:

Functional disorders

1. Amenable to nonsurgical methods
2. Demands surgical intervention to prevent organic change or to alleviate disfunction

Organic disease

1. Self-limited and better treated symptomatically
2. May be treated by drugs or nonoperative methods
3. Surgery indicated for cure
4. Morbid changes too far advanced for cure
5. Palliative procedures desirable

permeable membranes. A homogeneous, pore-free masslike gelatin and most proteins absorb liquids, undergoing an increase in volume—this is called molecular imbibition (Fick).

Serum is the liquid part of the blood which separates after coagulation; chemically it is blood plasma from which the fibrinogen has been removed by coagulation. The scab which results from hardened serum is due to a process known as syneresis. All surface films have a contractile action. It is this contractile action which constitutes or is the expression of the surface tension. A blood clot results from the conversion of fibrinogen from a soluble form (hydrosol) into fibrin—an insoluble state (hydrogel). This process of contraction of gels with the separation of some liquid (which is a saturated solution of the material of one phase of the gel, generally the solid matter containing other substance in solution such as salts) is known as syneresis. When a blood clot contracts due to shortening of fibrin particles, serum is squeezed out; agar-agar and gelatin contract, giving rise to so-called water of condensation; likewise serum contracts, losing its water, and becomes hard. Collodion behaves in this manner also.

Fig. 1.—Healing by first intention (dog). The section was taken after forty-eight hours. The defect was filled with a blood clot, which was lost in making the section. There is less cellular response in the superficial (left) than in the deep portion (mesodermal) of the wound (right)

The body fights with chemical substances (antibodies) and living cells (phagocytes). When an injury occurs, chemical substances (H-substance of Lewis; bacterial toxins, potassium from injured cells, peptones and other split proteins) and nerve reflexes warn the body of its presence. These start the process known as inflammation, which is sustained by an increase in local acidity (caused by relative anoxia, increased percentage of carbonic acid, and concentration of metabolic end products).

Inflammation is chiefly the reaction of mesodermal tissue. Epithelial cells have no phagocytic or other defensive powers and respond to an irritant by degeneration or disintegration as in leucoplakia and hyperkeratosis. But they do have the power of hyperplasia and hypertrophy which may be orderly as seen in repair or disorderly as seen in neoplasia.

PART II

LOCAL RESPONSE AND GENERAL BODY REACTIONS TO INJURY

Chapter 3

REPAIR—THE REACTIONS OF TISSUE TO MECHANICAL TRAUMA

In its broadest sense this entire book is a study of repair. Whether damage is done by mechanical, bacterial, or chemical causes, by neoplasia, or even by normal wear and tear, the process of healing is involved.

In every instance we are not only interested in the cause of the injury but more perhaps in the manner that tissues react to the insult, even in the case of neoplasia.

Living things are different from inanimate objects in many ways. The former have the power of growth, reproduction, the ability to metabolize food for the nourishment of their cells or tissues, and the faculty of repairing any defects which may occur.

Nature usually restores continuity by like or unlike tissue, but she may not always restore function of tissue. *Repair* may be defined as the ability of living matter to restore itself to a sound or good state after injury. There are several methods of repair.

Healing by First Intention, or Repair of Aseptic Closed Wounds.—An incision made with a clean sharp instrument induces a minimum of trauma and represents the ideal wound for healing by first intention. First there is some bleeding. Within about four minutes this blood, which has been pouring out, clots. Fibrinogen, which changes to fibrin, is responsible for clotting of the blood (see Chapter 13). Within three or four hours an exudate begins to form. It comes from the blood vessels and tissues that surround the wound and is composed partly of fluid (blood plasma, serum, and lymph) and partly of cells. Plasma is important because it helps combat infection. The serum is also important because forms a scab or crust when it dries and gets hard—nature's antiseptic and impermeable dressing. Lymph carries larger protein molecules and particulate matter to neighboring nodes and ultimately back to the blood stream.

Protoplasm may be regarded either as a very viscid sol or as a gel. Its structure is that of a microscopic emulsion. It can contract and thus press out a solution or it can take up water. In a porous mass such as porous clay, water is taken up in the previously formed spaces. Plants and animals take up fluid by osmosis through

permeable membranes. A homogeneous, pore-free masslike gelatin and most proteins absorb liquids, undergoing an increase in volume—this is called molecular imbibition (Fick).

Serum is the liquid part of the blood which separates after coagulation; chemically it is blood plasma from which the fibrinogen has been removed by coagulation. The scab which results from hardened serum is due to a process known as syneresis. All surface films have a contractile action. It is this contractile action which constitutes or is the expression of the surface tension. A blood clot results from the conversion of fibrinogen from a soluble form (hydrosol) into fibrin—an insoluble state (hydrogel). This process of contraction of gels with the separation of some liquid (which is a saturated solution of the material of one phase of the gel, generally the solid matter containing other substance in solution such as salts) is known as syneresis. When a blood clot contracts due to shortening of fibrin particles, serum is squeezed out; agar-agar and gelatin contract, giving rise to so-called water of condensation; likewise serum contracts, losing its water, and becomes hard. Collodion behaves in this manner also.

Fig. 1.—Healing by first intention (dog). The section was taken after forty-eight hours. The defect was filled with a blood clot, which was lost in making the section. There is less cellular response in the superficial (left) than in the deep portion (mesodermal) of the wound (right).

The body fights with chemical substances (antibodies) and living cells (phagocytes). When an injury occurs, chemical substances (H-substance of Lewis; bacterial toxins, potassium from injured cells, peptones and other split proteins) and nerve reflexes warn the body of its presence. These start the process known as inflammation, which is sustained by an increase in local acidity (caused by relative anoxia, increased percentage of carbonic acid, and concentration of metabolic end products).

Inflammation is chiefly the reaction of mesodermal tissue. Epithelial cells have no phagocytic or other defensive powers and respond to an irritant by degeneration or disintegration as in leucoplakia and hyperkeratosis. But they do have the power of hyperplasia and hypertrophy which may be orderly as seen in repair or disorderly as seen in neoplasia.

More capillaries open, there is an increase of blood to the part (*active hyperemia*), and cells and plasma are poured forth (exudation). This exudate consists of leucocytes (to fight infection); phagocytes, consisting of macrophages, histiocytes, and other reticulo-endothelial cells (to carry away debris, thus performing nature's débridement); fibroblasts (to produce collagen and ultimately fibrous tissue); and endothelial cells (to form new capillary loops).

Menken showed an increased permeability of the capillaries in inflammation, permitting plasma to escape into the injured area. The exudate is rich in fibrinogen and globulin.

The granular leucocytes (which are formed in the bone marrow from myeloblasts) migrate out of the vessels at the beginning of inflammation and then rapidly degenerate in the tissues. They are capable of engulfing cellular debris and digesting it within their substance due to leucoprotease. The wound contains cellular and other debris which is removed by autolysis (tryspin and pepsinlike enzymes from dying cells) and heterolysis, a function of leucocytes which also liberates leucoprotease which acts like trypsin and erepsin. Their action is inhibited by antienzyme of blood serum.

Phagocytes, also called mononuclear exudate cells, or polyblasts are said to arise from endothelium, macophages, blood lymphocytes, or monocytes. Polyblasts also arise from histiocytes. They are mononuclear and nongranular. Their function includes ameboid movement and phagocytic action and they are capable of becoming fibroblasts. Together with the fibroblasts they migrate along the fibrin filaments due to differences in electrical potentials (stereotropic response).

Fibroblasts keep their original nature and function; that is, they do not give rise to other cells except fibrocytes. They develop from reticuloendothelial cells, monocytes, macrophages, and endothelial cells. Although fibroblasts play a role in the formation of collagen, the polyblasts are probably chiefly concerned in the formation of this material. Fibroblasts become fibrocytes in collagen. This substance is derived from precollagen, which appears about the fifth day and takes the silver stain. It is immature and has little cohesive power. On the tenth to twelfth day collagen appears. It does not take the silver stain, is mature, and affords strength to the wound.

Many theories exist as to the origin of this substance. Haidenheim believed that connective tissue fibers develop in a peripheral ectoplasm which takes the form of a syncytial spongework. In such a syncytium argyrophilic networks appear as a result of vital metabolism of the syncytium itself. Maximow thought that the connective tissue fibers result from a crystallization of a semifluid, amorphous, secreted substance which occupies the intercellular spaces. Baitsell stated that the fibrin net fuses and consolidates into wavy fibrils which unite to form wavy bundles. The cells are first round, then flat, and then spindle shaped due to pressure of collagen bands. The substance is probably extracellular in origin.

Wound healing, then, is due to fibroplasia which results from resting undifferentiated cells closely related to the mesoblast. The differentiation of the fibroblasts into specific adult tissue is the result of, and occurs in the same manner as, the structures originally changed from embryonic mesoblastic tissue to adult fibrous tissue.

The cells go to work at their respective tasks. The fibrin in the blood clot acts as a scaffold for them to work upon. This period lasts about four to five days and is known as the lag period. The wound is weak and gains no strength during this time. About the fifth or sixth day large numbers of fibroblasts and endothelial cells appear (proliferative phase). Many causes have been suggested for this sudden stimulus. Some of these are

anoxia, embryonic tissue juice from new cells (trephones), protein split products, glutathione, hemoglobin, sulfhydryl group—SH, and wound or intercellular hormone. Perhaps it is not a stimulation of cells, but, as in the case of neoplasia, perhaps it is a controlled release of the inhibition which normally keeps fibroblasts from proliferating.

The fibroblasts are sparsely present for about four days and then are suddenly seen in large numbers. Their function is to form collagen, a soft gelatinous substance. It is reddish-yellow in color and becomes more red as new capillaries form and fill with blood.

Endothelial cells come from the ends of cut capillaries. They have motility and digestive powers and invade the fibrin mesh. They arrange themselves in parallel rows and unite the capillaries of the two sides and then become canalized, forming new capillary loops. This canalization is due to clot retraction, hydrostatic pressure, and collateral formation.

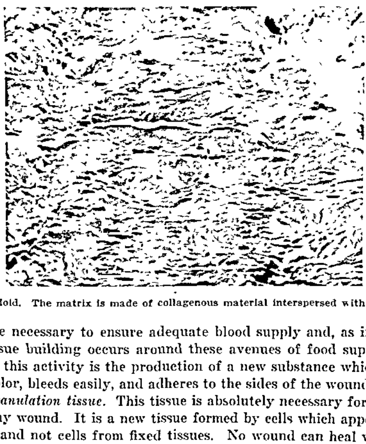

Fig. 2.—Keloid. The matrix is made of collagenous material interspersed with fibroblasts.

These are necessary to ensure adequate blood supply and, as in the embryo, tissue building occurs around these avenues of food supply. The result of this activity is the production of a new substance which is soft, red in color, bleeds easily, and adheres to the sides of the wound. This is called *granulation tissue*. This tissue is absolutely necessary for the healing of any wound. It is a new tissue formed by cells which appear in the exudate and not cells from fixed tissues. No wound can heal without it and having fulfilled its purpose it changes to scar tissue. If there is too much granulation tissue around the wound, the laity call it "proud flesh." Excessive scar tissue (keloid) is really a fibroma and exists not only in epithelial but in other tissues as well. For example, Dupuytren's contracture of the palmar fascia is probably due to a keloid of this substance.

With granulation tissue filling the wound, the epithelial cells begin their work under the protective crust of serum that has formed over it. *The epithelial cells on either side of the wound grow across and cover the granulation tissue (epithelialization).*

Epithelial cells show some ameboid movement. The cells get their stimulation from adjacent cells. At first there is only one layer—stratum germinativum. *In skin grafting this is the layer that is most commonly transplanted* and depended upon, although the whole skin may also be used. The stratum granulosum and lucidum could possibly grow due to plasma from granulation tissue. Epithelialization begins after a latent period of three to six days. Frequent dressings or antiseptics may prolong this by tearing away or devitalizing the advancing cells. Howes stated that the average *rate of epithelialization over recently formed granulations is 1.5 mm. daily*. The rate is not influenced by the size of the wound, nor is there a greater rate after the start than at ten days. There is no particular rhythm or rate; sudden "bursts" of activity occur. Local conditions may slow it and infection stops epithelialization entirely. Microscopically it is characterized by (1) hypertrophy of uninjured epithelial cells at the edge of the wound; (2) the migration of these cells outward over a suitable granulating base; (3) mitotic division; and (4) restratification, which will be slower where the skin is thick (palms and soles). Tropism is not seen.

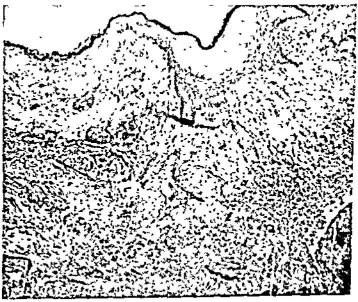

Fig. 3.—Healing by first intention (dog). *Fourteenth day* Epithelialization is complete. There is a minimum of scar tissue. Experiments have shown that a pure culture of staphylococcus, rubbed on an operative wound in an experimental animal after the first day, will almost invariably be followed by an *infection leading to septicemia* and often death of the animal. If this same procedure is repeated after the development of local immunity, which occurs about the eighth day in aseptic wounds, and about the eighth to tenth day in those that are primarily infected, *no local or systemic reactions* occur. Surgeons apply this fundamental principle in everyday practice by not molesting or disturbing the wound for about eight days They also depend upon this phenomenon in removing stitches. The aseptic technique formerly used in *this procedure is unnecessary if trauma is not inflicted.*

After four or five days the wound is filled with fibroblasts and little gray collagen fibers appear. The collagen soon begins to shrink and gets harder. *The strength of the wound increases daily:* healing is about one-third complete on the sixth day, two-thirds by the eighth day, and almost complete by the fourteenth day. Scar tissue forms from collagen, and

as it contracts it squeezes the newly formed capillaries which have made the wound appear red; in about six months they are completely occluded, making the scar white. This is known as healing by first intention, or healing with a minimum amount of granulation tissue.

Scar tissue is, in reality, a substitute for injured or destroyed tissues. Lacking tone, it often stretches under tension. Surgeons should follow natural creases or wrinkles and should know the direction of elastic fibers in the skin so that incisions may be made parallel with them, thereby avoiding wide scars.

The skin is composed of ridges and sulci. From the latter emerge the hairs. Esricht of Denmark first plotted the hair lines in 1837. Later Langer plotted skin tension lines by making small holes in the cadaver and examining the separation of their edges. Kocher later made tiny incisions and checked their separation. These followed the direction of the connective tissue strands in the dermis and the hairs in the epidermis.

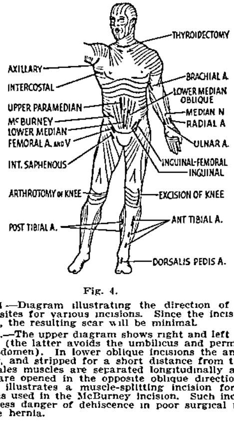

Fig. 4.

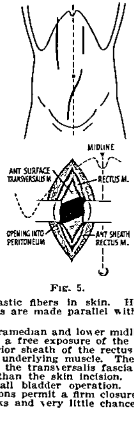

Fig. 5.

Fig. 4.—Diagram illustrating the direction of elastic fibers in skin. Heavy lines indicate sites for various incisions. Since the incisions are made parallel with the elastic fibers, the resulting scar will be minimal.

Fig. 5.—The upper diagram shows right and left paramedian and lower midline oblique incisions (the latter avoids the umbilicus and permits a free exposure of the pelvis and lower abdomen). In lower oblique incisions the anterior sheath of the rectus is divided obliquely, and stripped for a short distance from the underlying muscle. The recti and pyramidales muscles are separated longitudinally and the transversalis fascia and peritoneum are opened in the opposite oblique direction than the skin incision. The lower diagram illustrates a muscle-splitting incision for gall bladder operation. The same method is used in the McBurney incision. Such incisions permit a firm closure, with infinitely less danger of dehiscence in poor surgical risks and very little chance for postoperative hernia.

This same principle applies to abdominal incisions for surgical procedures. They are made parallel with the muscle or fascia rather than across it. However, transverse incisions in the upper abdomen cutting across the rectus abdominis are useful and strong, because the transversalis aponeurosis is cut in the direction of its fibers and the rectus sheath is easily approximated. The nerve supply must not be interfered with. This also is a factor in planning incision, especially about the face.

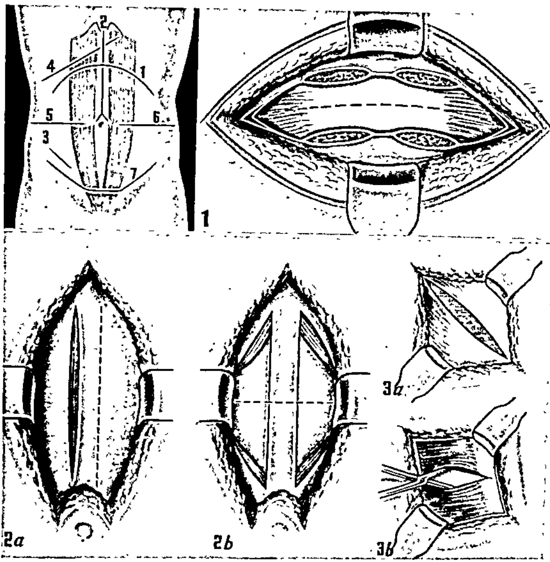

Fig. 6.—The upper left diagram illustrates various sites for abdominal incisions.

1. Transverse incision. This is useful in operations on the stomach, transverse colon, common bile duct, and pancreas. The inverted U-shaped line roughly follows the costal margins. This incision provides for a strong closure and is especially useful in "lateral type" persons whose transversalis fascia fibers run almost horizontally.

Upper right shows the anterior sheaths and both recti divided. The obliques have also been cut on each side. The transversalis is then divided transversely in lateral types or in an inverted U manner in linear types.

2. Midline incision. Many surgeons prefer a right or left paramedian cut so that a cuff of the anterior rectus sheath is left mesially. The incision affords access to the entire upper abdomen, and when it is made slightly paramedian and slanting lateral to the left, the lower esophagus may also be brought into view. When slanted to the left or right into the eighth interspace, a combined thoracoabdominal exposure results. The diaphragm is divided, and on the left side such operations as total gastrectomy, lower esophagectomy, splenectomy and nephrectomy in difficult cases are greatly simplified. On the right, the pancreas and portal vein are easily exposed, facilitating such operations as resection of head of pancreas, portacaval anastomosis, and liver resections. Closure of the transversalis fascia is not difficult because in "linear type" persons the fibers run more obliquely downward than transversely. The right paramedian incisions are used for stomach, pancreas, gall bladder, right colon, and liver operations. *2a* shows a more anatomical incision than the upper midline or the right or left oblique paramedian. The Sloan incision, as it is called, divides the anterior sheath of the rectus on each side of the midline. The recti are retracted laterally and then the transversalis fascia is cut transversely or in the direction of its fibers as shown in *2b.* Sloan found that in longitudinal incisions, the longer the cut, the more force was required to bring the ends of the divided aponeuroses together. The lateral pull on the suture line is in proportion to the square of the length of the incision. When relaxation is not complete, the lateral abdominal tension is about thirty times as great in the vertical as that on the

(Continued on opposite page)

The scar contracts equally in all directions and the final result is a fine white line, like normal skin except for the absence of hair follicles, sebaceous glands, and sweat glands. This is known as *cicatrization* and the scar is called the *cicatrix*.

Healing by Second Intention.—The wound healing by second intention takes exactly the same course as that healing by first intention with one exception—it requires a greater amount of granulation tissue.

If, for any reason, a wound is delayed in its healing, it does not heal "straight across" but heals from the "bottom up." These terms are really misnomers because all wounds must heal in all parts to obtain complete union. It is better to say that more than a minimum amount of granulation tissue is needed to secure repair. The process is exactly the same but a larger area must be filled in with something that will reestablish continuity. This is granulation tissue. For example, the most common cause of *healing by second intention is infection. As we shall* learn later, bacteria destroy cells, leaving large defects in the tissues. Repair cannot be completed as long as the infection continues because the bacterial toxins will destroy all attempts at repair. The process of repair is the same as in the healing by first intention; however, a larger number of polymorphonuclear leucocytes and macrophages will be found among the cells in the exudate. We have seen that inflammation is necessary to obtain repair of tissue, but repair will not occur unless a *local immunity* is established which annihilates the bacteria, or, more correctly, creates an environment unfavorable for bacterial growth, permitting the local immunological agents to destroy the invading organisms. Thus inflammation and repair are not synonymous, and inflammation and immunity are not the same. Inflammation may occur without repair but the reverse is not true, and in order to secure repair in an infected wound it is necessary to have inflammation and immunity.

Repair begins shortly after injury. It differs from bacterial inflammation in its immunological qualities and its anatomical appearance. A pyogenic membrane is produced by the exudates of inflammation, aided by the forces of repair and immunity,

---

suture line of the transverse incision. (Sloan, G. A.. A New Upper Abdominal Incision, Surg., Gynec. & Obst. 45: 678, 1927. 2b. Incision through the transversalis fascia.

3. *McBurney incision. An anatomical incision usually employed in operations on the* appendix or cecum. 3a. The external oblique fascia is divided in the direction of its fibers. 3b. The internal oblique and transversalis muscles are split in the direction of their respective fibers, then the peritoneum is opened obliquely parallel with the skin incision or transversely.

4. Subcostal incision. Used in gall bladder and bile duct operations.

5. Right-sided transverse incision. Used for approach to the ascending colon and cecum; also in right lumbar sympathectomy (extraperitoneal). The incision in the last instance is muscle splitting, that is, the transversalis sheath is incised and the rectus muscle pulled medially, and then the obliques and transversalis muscles are split in the direction of their fibers.

6. Left-sided transverse incisions are useful in operations on the descending colon and spleen and in left lumbar sympathectomy.

7. Low transverse incision (Bardenheuer). All of the layers of the abdominal wall are cut transversely. Pelvic surgery of all types may be done through this incision. The central and left components of this incision are used in abdomino-perineal resection of the rectum and anterior resections of the sigmoid. The Pfannenstiel incision cuts only the skin and fascia transversely.

and serves to limit infection. It may be looked upon as a special type of granulation tissue (Chapter 4). When bacteria can no longer invade and destroy it, the wound becomes filled with it, permitting repair.

The entire process has been compared by MacCallum to a burning house.

The fire is destroying the house very rapidly. The alarm is sounded (chemical and nerve reflexes), firemen appear (leucocytes) and attach many lines of fire hose (new capillaries and endothelial cells) which bring water (blood cells and plasma), and

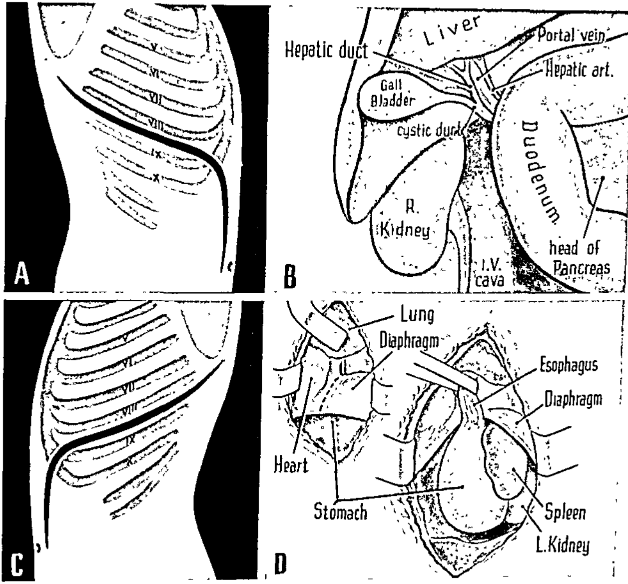

Fig. 7.—Thoracoabdominal incisions. *A.* Right Thoracoabdominal exposure. *B.* This permits easy access to the entire upper right quadrant and is particularly useful in such operations as hepatic lobectomy, repair of stricture or repair of destruction of the biliary duct system, excision of liver neoplasms, portacaval shunts, and pancreatectomy. *C,* Left Thoracoabdominal exposure. *D.* This is extremely useful in surgery of the esophagus, cardiac end of the stomach, spleen, left kidney and adrenal gland, and tail of the pancreas.

Recently we have been using an incision which is a combination transverse and thoracoabdominal with excellent results. It is made in the direction of the eighth interspace and carried upward.

chemicals (antibodies). Carpenters start the process of reconstruction (fibroblasts). Of course, if the fire breaks out anew, the new material will be destroyed again (destruction of granulation tissue); but if it is extinguished, *their efforts will ultimately reconstruct the dwelling*. It will not be perfect in material or contour (absence of hair follicles, sebaceous, and sweat glands; or cicatricial contraction) but will be serviceable and not too unsightly if the destruction is not too widespread. In the latter event a portion of the house may have to be rebuilt (surgical aid—skin graft—may be needed to prevent undue distortion).

Granulation tissue is insensitive at first because nerve fibers have not grown into it. This process begins in six to twelve weeks. After the wound has filled with granulation tissue, a little thin gray membrane creeps across the top; this is the new skin (epithelial cells which are really the first layer of the stratum germinativum). Finally it grows across and the wound is healed. Later the epithelium becomes stratified in the skin and mucous membranes. The connective tissue within the wounds forms the *scar or cicatrix, which contracts equally in all directions* (length, width, and depth). This structure is weak and may stretch

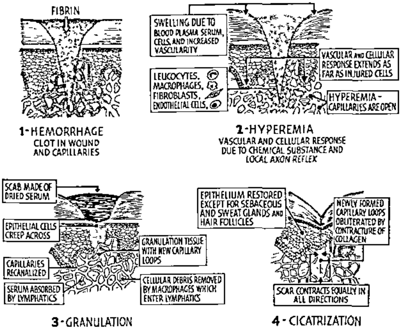

Fig 8.—Diagram indicating stages in wound healing. It must be understood that these events do not occur chronologically, as independent stages, but that they overlap; however, it may be said that by the fourth day fibroplasia has begun, and by the end of two weeks healing is normally complete.

1. Immediately after an incised wound is made there is bleeding. Clotting occurs due to fibrin.

2. The tissues react to the injury by increasing the blood supply to the part (hyperemia) and by the attraction of cells. This response may be due to chemotactic or nervous influence or to a local, axonal reflex dilatation of the capillaries. Cells are shown in the lumina of the capillaries and around them.

3. Stage of granulation. Capillaries are recanalized and have grown across into the granulation tissue, making it red. Plasma and serum are absorbed by the lymphatics. Epithelium is creeping across the granulation tissue under the protection of the scab which hardens due to syneresis. The epithelium is at first one cell-layer thick, and this is the stratum germinativum. From these cells the other layers develop in stratified squamous epithelium. The stratum corneum may take a long time to form in such thick skin areas as the soles of the feet and the palms of the hands.

4. Cicatrization. Contraction occurs in length, width, and depth.

processes or changes in hydrostatic or osmotic pressures. The latter includes cells and plasma which migrate through dilated and more permeable capillaries. It is apparent that the former will contain less protein because this molecule is too large to traverse the normal capillary wall. It is the distention of tissue spaces with the fluid preventing proper blood supply and tissue cell migration rather than the characteristic of the transudate which delays healing.

Epithelization sometimes occurs before granulation tissue fills the gap. This leaves a *dead space* which fills with serum or exudate. It will open again, for healing must be from the bottom up.

Healing by Third Intention.—Healing by third intention was reintroduced during World War I. In this case the surgeon brings together by suture or butterfly of adhesive tape two walls covered with healthy granulation tissue. (The fact that local immunity has been established must be shown by a minimum amount of pus and active proliferation of granulation tissue.) By this method much time can be saved in the healing process, through probably, immobilization of the wound's edges and a reduction of its size.

FACTORS WHICH INFLUENCE THE HEALING OF A WOUND

1. Infection
2. Size of the wound
3. Blood supply (passive congestion and anemia)
4. Rest
5. Foreign bodies
6. General condition of the patient
7. Miscellaneous causes

Infection.—*All wounds are contaminated.* This means the presence of bacteria at the site of injury; but *the mere presence of bacteria does not constitute infection.* If the wound is properly cared for within six to eight hours, infection may not occur. Infection delays healing until immunity occurs and the infection is annihilated. The healing takes place by second intention. If the infection is not overcome, healing will not take place, granulations will become fibrosed (cicatrization), and chronic ulcers will form. Surgeons guard against infection in surgery by using an "aseptic" technique and in contaminated wounds by thorough cleansing (see Chapter 16).

The technique of modern surgery is nearly aseptic. In spite of the most rigid cleansing and disinfection of the abdominal wall, some residual bacteria remain in the hair follicles and sebaceous gland ducts, although the "transient" flora of bacteria have been removed. Furthermore, due to bacteria in the air of the operating room and those which escape careful masking of the surgeon's face, a surgical wound contains more bacteria at the conclusion of an operation than at its beginning. In addition, the surgeon's hands, although carefully scrubbed and disinfected with 70 per cent alcohol (supposedly the most efficient disinfectant for this purpose), will show more bacteria after gloves have been worn for the dura-

subsequently under pressure. In the abdomen this may give rise to hernia. It is important to emphasize the fact that *the greater the delay in healing, the more granulation tissue; and the more of this, the greater the scar and the subsequent contracture;* the more trauma or injury, the greater the delay. Surgeons therefore, handle tissue gently and carefully, because they know that *healing occurs in inverse ratio to the degree of trauma.*

An incision for the performance of a surgical operation should be made as close to the site of the disease as possible. This minimizes trauma.

A. B.

Fig. 9.—Healing by second intention. *A.* Rabbit's tongue. No suture used. The mucous membrane dips down into the wound. There is a wide scar. *B.* Edge of burn. Granulation tissue has filled the defect.

Any factor which increases the exudative reaction beyond normal causes a delay in healing. This delay may be due to local factors such as infection, mechanical or chemical trauma (strong antiseptics, local use of sulfonamides, talcum powder, etc.), foreign bodies (dead tissue, blood clot, large amounts of suture material, especially catgut, and, in the presence of infection, nonabsorbable sutures perpetuate the delay until extruded), and extremes in temperature, whether cold or hot. The general factors causing an increase in exudation include low osmotic pressure of the blood due to hypoproteinemia or hydremia, which may be due to hyperhydration; dehydration with stagnant anoxemia and leaky capillaries; anoxemia; general debility as seen in advanced carcinoma (cachexia) which is really a combination of many factors, q.v.; also allergy to catgut has been suggested by experimental and chemical reports. Thus we see that transudates as well as exudates may delay healing. The former may be looked upon as the fluid part of the blood leaving normal capillaries because of normal physiological

healthy granulation tissue. Vascularization takes place through the capillary loops in this tissue. Some or all of the stratum germinativum is taken, and from this, as in normal repair, restratification occurs. Undoubtedly, transplanted cells from the stratum granulosum and even lucidum may survive. The more common types of free grafts are: Reverdin (pinch), which are usually placed on the surface but may be buried in the granulation tissue; Ollier-Thiersch, or the thin split graft; thick split graft and Wolfe-Krause, which is a full thickness of the *skin* containing dermal elements as well. The split graft may be used on most raw surfaces and has the advantage of leaving part of the stratum germinativum on the donor *site*, thereby avoiding its grafting.

FIG. 11.—Extensive burn covered with infected crusts. These must be removed so that healthy granulation tissue may form. The area is then covered with Thiersch or split-thickness grafts.

An ingenious method of maintaining the position and contact of a free graft has been devised by Sano. He employs the patient's own blood, using the buffy coat (white cells) after centrifuging. These cells are mixed with Tyrode's solution (a buffered salt solution) and the cell mixture or extract is applied to the undersurface of the graft. Large split-thickness grafts are usually immobilized by silk sutures; then immobilization of the part is secured by casts or splints and pressure bandage.

When large deep areas must be built up, *pedicle* grafts are used. A flap of skin may be used or simply *transplanted by parallel or Z incisions, leaving its end or ends*

tion of the average operation. These considerations have led to "soap and water" cleansing of the abdominal wound before closure, ultraviolet radiation of the surgical room, more efficient face masks, change of gloves and "second scrubbings" in the longer operations, etc., as we shall see in Chapter 5. Ultimately the development or nondevelopment of infection depends on the resistance of the patient's tissue cells. *If local immunity* is normal, a minimal number of contaminating organisms will be harmless. If devitalization occurs due to extensive trauma, the devitalized tissue wherever possible should be excised. Still more desirable is atraumatic *surgery*.

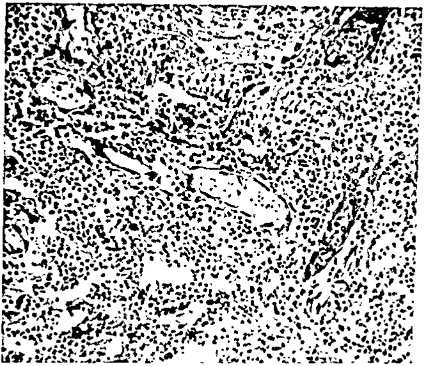

Fig. 10.—Granulation tissue from an infected wound. There are many capillary loops. Fibroblasts, polymorphonuclear leucocytes, lymphocytes, and macrophage cells are present in large numbers.

Size of Wound.—In large burned areas, for example, in which infection has been overcome, healing is also delayed. The epithelium can grow only across a certain distance, which is variable but for unknown reasons limited. Some believe this is due to lack of chemotactic influence. As scar tissue contracts, the size of a wound becomes smaller, permitting epithelialization to occur. *As uncovered granulation tissue* grows older, it contracts, obliterating the newly formed capillaries and ending in a pale, fibrosed bloodless mass of tissue which does not fill in the defect. This is the formation of what is known as an *ulcer or sore.* After extensive burns, skin grafting is done on the healthy granulation tissue as soon as it fills the wound, thereby preventing vicious scars or ulceration and hastening healing.

There are many ways of transplanting skin from one part of the body to another (autogenous). Although sporadic reports of *successful isogenous, homogenous, and* even heterogenous skin grafts appear, we have been unable to duplicate these feats. *Free* grafts imply the complete separation of the donor skin and its transplantation on

healthy granulation tissue. Vascularization takes place through the capillary loops in this tissue. Some or all of the stratum germinativum is taken, and from this, as in normal repair, restratification occurs. Undoubtedly, transplanted cells from the stratum granulosum and even lucidum may survive. The more common types of free grafts are: Reverdin (pinch), which are usually placed on the surface but may be buried in the granulation tissue; Ollier-Thiersch, or the thin split graft; thick split graft and Wolfe-Krause, which is a full thickness of the *skin* containing dermal elements as well. The split graft may be used on most raw surfaces and has the advantage of leaving part of the stratum germinativum on the donor site, thereby avoiding its grafting.

Fig. 11.—Extensive burn covered with infected crusts. These must be removed so that healthy granulation tissue may form. The area is then covered with Thiersch or split-thickness grafts.

An ingenious method of maintaining the position and contact of a free graft has been devised by Sano. He employs the patient's own blood, using the buffy coat (white cells) after centrifuging. *These cells are mixed with Tyrode's solution (a buffered salt solution)* and the cell mixture or extract is applied to the undersurface of the graft. Large split-thickness grafts are usually immobilized by silk sutures; then immobilization of the part is secured by casts or splints and pressure bandage.

When large deep areas must be built up, *pedicle* grafts are used. A flap of skin may be used or simply transplanted by parallel or Z incisions, leaving its end or ends

attached. Tube grafts are rolled flaps of skin which are "waltzed," "jumped," or "caterpillared" into position by successive planned implantations leading to the final destination. Inlay grafts (Essen) are split-skin grafts on molds which are buried raw side out in the tissues and then later opened and transplanted to conform to a cavity about the eye or mouth. Tunnel grafts are whole-thickness transplants beneath the skin.

Combination grafts are also known as delayed pedicle grafts. Here the blood supply is poor and the pedicle of skin is elevated and then returned to its former position so that its blood supply will be increased and granulation tissue may form on its undersurface. Such grafts may be lined with thick split grafts and used to reconstruct the cheek, nose, etc.

Fig. 12.—Vicious cicatrix due to a burn. The deformity was corrected by forming a tube graft (jump, waltz, or caterpillar) on the abdomen and "waltzing" it into position. Then when ready to sew down, the scar was excised and the graft opened and sutured into the excised area.

Other tissues may also be freely transplanted. These are mucous membrane, fascia, tendon, cartilage, and bone. Fat is used as a free transplant but is perhaps more successful if on a pedicle. A whole muscle not deprived of its blood supply is frequently transplanted in orthopedic surgery; also in chest surgery to fill in large empyema cavities. Homogenous grafts of cartilage, corneal tissue, bone, and even organs such as veins and arteries have been successfully used.

Epithelial *grafts send out cells which join the grafts to each other* and to the wound margin. Thus it will be seen that the size of the wound may delay healing even if there is no infection; and the more the delay, the more granulation tissue; the more granulation *tissue, the greater* the scar; and the more scar, the more contraction. When vicious con-

tractures occur, the surgeon must start from the beginning, remove the scar surgically, and then perform a skin graft or a tube graft operation.

Blood Supply.—Tissues must have an adequate blood supply in order to heal. Anemia of tissue may not only delay healing, but cause sloughing as well. Sloughing is often caused by plaster casts applied too tight and allowed to remain on for long periods without careful inspection.

Fig 13.—Thiersch grafts in place. Note the free movement of the arms.

Wounds may break open because sutures were put in too tight by the surgeon. Sutures should be tied loosely and a wound should never be sutured under tension It is far better to make skin flaps or leave the area for subsequent skin grafting. The same principle holds in all tissues and organs. If there is a poor blood supply due to arterial disease, such as arteriosclerosis or thromboangiitis obliterans, the wound will be very slow to heal. It is important to test the blood supply of the extremities in the aged and those afflicted with diabetes before during operations on the feet.

Therefore, when a patient with arterial disease develops gangrene, necessitating the amputation of a lower extremity, the surgeon should amputate at the thigh if necessary, where the blood supply is adequate for good wound healing (see Chapter 6).

Blood stasis delays healing. A wound in the lower tibial region is very slow to heal. Standing produces a certain amount of passive congestion in the legs. Waste products cannot get away; fresh blood cannot get in. This is *stasis with resulting asphyxia of tissue, and it not* only prevents healing, but in certain conditions causes devitalization as well. Patients with varicose veins have much more stasis than normal individuals, for no valves are present in these veins. Such patients usually come to the surgeon with a history of a small scratch which will not heal. An elastic bandage should be applied in all cases of leg wounds,

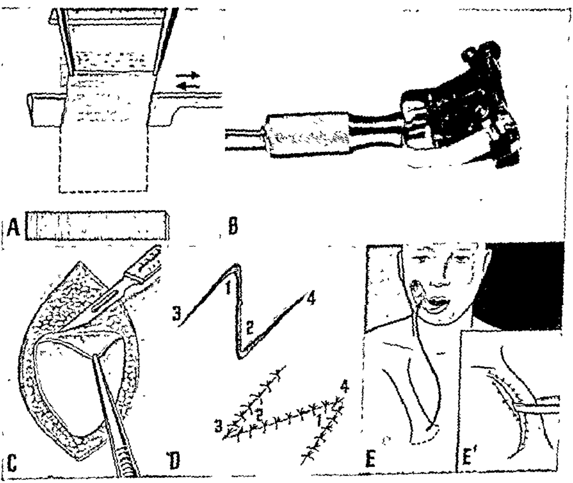

Fig. 14.—Diagram illustrating various methods of skin grafting and Z-plasty. *A.* Split-thickness graft. *B* The Brown electro-dermatome *C. Reverdin graft. D. Z-plasty.* A useful procedure in the treatment of contractures due to vicious cicatrization. Although the illustration shows only one Z, the operation may be extended to two or more Z maneuvers. *E* and *E'* *Pedicle graft.* The plan of a pedicle is based upon the preservation of an adequate blood supply in the two attached ends, if the graft is fashioned in line with a blood vessel such as the superficial epigastric, the distal end may be detached and sewn into place as, for example, on the dorsum of the hand in one operation. Otherwise such grafts are moved after the blood supply has become established. One side is detached at a time so that the pedicles will be maintained during the "waltzing" maneuvers.

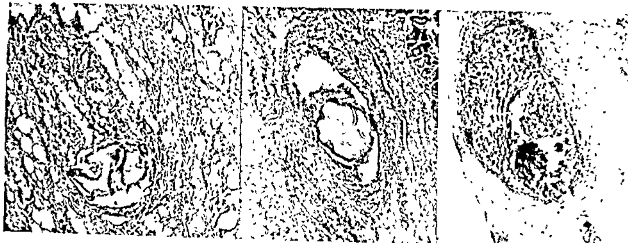

A. B. C.

Fig. 15—*Different types of suture material after ten days (dog).* A. Plain catgut There has been almost complete disintegration of the catgut. The tissue reaction is pronounced B. Chromic catgut No. 0 The suture is intact There is less reaction than in A. C Silk The strands of silk are slightly separated by serum. There is almost no tissue reaction. The same is true of cotton suture. Linen remains intact better than silk and causes even less reaction

even in normal individuals, thereby limiting stasis, so that normal repair of wounds may occur. It should be emphasized, however, that pressure should never be applied to such a degree that there results an interference with the blood supply. If this is done, the viability of tissues is endangered and within a variable period (twelve to seventeen hours) massive necrosis may occur.

Rest.—Needless to say, a wound cannot heal with a minimum amount of granulation tissue when the edges are in motion. A dog with a wound lies quietly in the sun and licks the raw surface. (Rest and cleanliness?) When a surgeon sutures a wound or puts a broken leg in a cast, he puts the two divided edges at rest. Rest to the part is necessary for healing, so that there will be a minimum of granulation tissue.

Wounds are sutured to obtain rest and immobilization, reduce trauma to their edges, and decrease the size of the gap until repair is complete. Various materials are available for wound coaptation. In general, it may be said that if the divided tissues can be held in apposition without the aid of sutures, this is desirable; for example, adhesive on the skin, a plaster cast, or splint for fractures. Two factors are important in selecting a suture—the type tissue involved and its condition (infected, contaminated, badly contused, or normal) and the qualities of the suture material (strength, reaction engendered, absorbability, ease of handling, sterilizing, and cost).

Two general types of sutures are used: absorbable (plain and chromic catgut, kangaroo tendon, fascia) and nonabsorbable (cotton, silk, linen, rayon, cellophane, and metals such as silver on tantalum wire, pins, and clips).

Even in normal tissues their structure is important in selecting a method of securing rest. For example, bone is not successfully held by sutures and, moreover, porous bone may require a large piece of metal. The ideal suture is one which will remain intact long enough to secure rest to the divided structures and which will cause a minimal reaction in the tissues. For this purpose in clean wounds cotton, silk, or linen may be used. For infected, badly contaminated or contused wounds, sutures are used to control bleeding and not to close the area unless thorough débridement is possible—in such instances catgut is best. Plain catgut causes great reaction and is quickly absorbed. It is therefore not so reliable as chromic catgut. Smaller sizes such as 0 and 00 last as long as, or longer than, larger sizes, for they are more thoroughly impregnated with chromic acid or iodine. Also, a double strand of small catgut engenders less reaction than a single strand of large suture, because it is harder for the tissue wandering cells to attack the former. In general, the more inert the material used, the less the reaction to it, and the less the reaction, the more rapidly healing will take place.

Strength of Suture Material.—Halsted's dictum, that it is not necessary to use a suture stronger than the tissues which are brought together, is true because it will be the tissue that will give under tension. All sutures lose tensile strength after implantation. The strength of chromic catgut is highest before implantation but lowest after ten days. Cotton is said to have the least tensile strength before and the most after ten days. Silk is weaker than catgut but stronger than cotton before and weaker than cotton after ten days in the tissues. There is little difference in the tensile strength between plain and chromic catgut.

Other Considerations.—Microorganisms are said to be found much more commonly (five times) in catgut sutured wounds than in silk sutured wounds. This is probably due to the irritation of the former permitting indigenous bacteria to grow. The lag period is longer in the former (catgut) because the suture is destroyed due to an acute inflammation which produces the prolonged "cellular débridement." There is also a delay in the maturation of fibroblasts and production of collagen due to the great

inflammatory reaction. Therefore, *the greater the reaction, the more exudation*, and the more the exudation, the greater the delay in fibroplasia. Some of the tissue reaction to catgut may be due to allergy (q.v.); irritation by the preservatives (xylene, alcohol, solvent naphtha, etc.) large knots required due to low coefficient of friction.

For uninfected wounds cotton or silk is ideal because of the small amount of exudation, ease of sterilization and handling, durability, and high coefficient of friction.

Removal of Sutures.—Skin sutures are almost always nonabsorbable because they do not produce stitch scars for reasons given. Skin sutures are usually removed in clean wounds on the eighth to the tenth day (see legend to Fig. 3). At this time local immunity is high, *and contamination, unless accompanied by gross trauma, will not result in infection.* Also, epithelialization is practically complete and scabs are ready to fall off. If sutures are removed too soon there may be separation of the skin edges and an infection may result. If left too long, some of the suture material (especially black silk *may become infiltrated with scar tissue and may be left in the wound as a* dark streak. Also, there may be considerable local reaction with resultant scars at the sites of the stitches and even across the wound (stitch scars). In surgery of the face and neck many devices have been used to avoid ugly scars. All of the factors which delay healing are avoided. *In addition, incisions are made in normal folds and held* by subcutaneous sutures of fine silk, or if cutaneous sutures are employed, they are removed early, about the fourth day, and opposition is maintained by a few subcutaneous sutures and by adhesive on the surface.

Foreign Bodies.—Wounds will not heal readily with foreign bodies in them. Drainage tubes are introduced in some cases deliberately to prevent healing for a time. Blood clots and devitalized tissue act as foreign bodies. Glass, dirt, grease, hair, etc., must be removed. Anything between the edges of a wound will delay repair. *Pieces of metal or silk, if sterile, may be enclosed within a wound, but not between its edges.* Silk sutures in sterile wounds, or even steel or other metal (wiring of fractures), may remain in a wound without delaying repair, and although the marrow cavity tolerates foreign bodies poorly, intramedullary pins are used successfully in treating fractures. If a piece of muscle lies between two ends of a broken bone, healing may be delayed. Therefore, the surgeon is careful to avoid foreign bodies to operative wounds, and in accidental injuries he is careful *to remove all extraneous material.*

Recently much has been written about *the dangers of talcum powder in surgery. The effects of this substance* have been studied in operative wounds in the brain, peritoneal cavity, vagina, rectum, and other tissues. The reaction is that induced by any sterile foreign body except that it is more vigorous due to its silicate nature because the body cannot readily repair the defects it induces. There is a tubercle-like formation around the granules which is ultimately replaced by fibrosis *and resultant scar. Vicious cicatrices may form, causing ugly scars or* dense adhesions in the peritoneal cavity. Some observers believe that silicosis may result. This is probably not true because little, if any, absorption occurs. Potassium bitartrate is now used in many hospitals, as first suggested by Selig, or starch mixtures may be employed.

General Condition of the Patient.— Dehydration (*due to vomiting,* diarrhea, or lack of fluids) or starvation (*with low blood protein and re-*

sultant edema) may delay healing. Formerly it was customary to starve patients three days before operation. This is not done now. Profound anemia, diabetes, or long debilitating disease adversely affects repair. Modern surgery demands thorough preoperative preparation for this reason. Attention is given to fluid and electrolyte balance (salt solution), nutrition (glucose), and plasma protein (blood and plasma transfusions) in this preparation. In addition, the necesssary vitamins are supplied.

Vitamin A deficiency may result in xerophthalmia. One of the first symptoms is nyctalopia, or night blindness. Minor disturbances of the skin (hyperkeratosis), decrease in general body resistance to infections, and retardation of body growth are also said to result from various amounts of depletions of this vitamin. The effect on mesodermal structures is not clear. Recent experiments on vitamin A-deficient animals show a delay in healing. The local application of cod liver oil apparently accelerates healing in these animals, but there is no proof that this is due to its vitamin A content. There is no evidence that the ingestion of vitamin A prevents the formation of renal calculi in man or that it is useful in the treatment of hyperthyroidism, anemia, nervous disorders, or ulcerations of the skin. The daily requirement is about 5,000 to 6,000 units.

Vitamin B complex is composed of the following substances: (1) thiamine (vitamin B_1, antineuritic antiberiberi factor); (2) riboflavin (vitamin B_2, vitamin G, a growth factor; (3) niacin (nicotinic acid or nicotinic acid amide, P.P. or pellagra preventive factor); (4) pyridoxine (vitamin B6, antidermatitis factor); (5) pantothenic acid (filtrate factor); (6) biotin (vitamin H, coenzyme R, anti eggwhite injury factor, needed for growth of yeasts, molds, and bacteria); (7) paraminobenzoic acid (antisulfonamide factor); (8) inositol; (9) choline; (10) folic acid.

Of these factors, thiamine and nicotinic acid are most important in surgery. The former is useful because its reduction causes an interference with glycogen storage and resultant hyperglycemia. Since it acts as a coenzyme in facilitating the oxidation of pyruvic acid in the body, an increase in the latter has been used as an indication of thiamine deficiency. It is especially indicated before and after thyroid surgery cardiovascular and nutritional effects, gastrointestinal surgery (intestinal effects), and biliary tract or liver surgery (diminished hepatic function causes a decreased ability of the liver to phosphorylate vitamin B for utilization by the tissue). Daily requirement is 1 to 2 mg. or 300 to 600 units.

Nicotinic acid is used before and after gastrointestinal surgery and especially where fistulas of the small bowel must be corrected. Pellagra may occur due to an inability to absorb the nicotinic acid factor or due to its loss through a fistulous opening before absorption can take place. Also, in all obstructive lesions (esophagus, stomach, upper intestinal canal) where parenteral feeding is necessary and in severe diarrhea (chonic ulcerative colitis) this factor must be used. The daily requirement is 20 to 30 mg. in normal adults. None of the B factors should be given alone over long periods because any of them given in large dosage will step up the metabolism of the others which, if not also supplied, will result in a deficiency. Thiamine chloride in large dosage is a method of producing vitamin B deficiency in experimental animals.

Vitamin C, ascorbic acid, also known as cevitamic acid, is the antiscorbutic vitamin. There is no proof that its deficiency causes dental caries, pyorrhea, or gum infections or predisposes to anemia, undernutrition, or infection. Its deficiency does interfere with wound healing because precollagen, devoid of holding power, may be laid low down instead of collagen. The production and maintenance of the intercellular cement substance may be impaired. Bleeding tendencies are said to be due in part to the deficient intercellular structure of blood vessels. It is well to emphasize that deficiency symptoms as just described do not occur until five months on a vitamin C-free diet. Wounds heal normally in subjects on a scorbutic diet for six months. However,

in chronic gastrointestinal disease, where intake is inadequate, or in patients with intestinal fistulas or chronic diarrhea, ascorbic acid should be given pre- and postoperatively. The daily requirement in normal persons is 75 to 100 mg.

Vitamin D probably represents more than one substance. A deficiency may interfere with the proper utilization of calcium and phosphorus, causing rickets, spasmophilia (infantile tetany), and osteomalacia. The vitamin may be important in tooth formation and maintenance and indirectly with blood clotting (calcium metabolism) and the repair of bone.

Calciferol (vitamin D_2) is irradiated ergosterol. Daily requirement for growing children or during bone repair is 400 units.

Vitamin K *is necessary for the synthesis of prothrombin which is formed in the* liver. Its deficiency produces hemorrhagic tendencies due to a hypoprothrombinemia. Vitamin K_1 is manufactured by the green leaf and chlorophyll-containing plant organs (alfalfa, spinach, etc.). It is therefore obtained by the ingestion of such plants. Vitamin K_2 is formed during the course of putrefaction and is formed in man in the large intestine. Vitamin K is therefore available at all times from exogenous or endogenous sources in the normal individual. It is indicated in (1) prolonged dietary deficiencies; (2) obstructive jaundice; (3) primary hepatic disease; (4) hemorrhagic states which exist in chronic intestinal diseases, whether due to loss of continuity (fistula) or absorptive surface (chronic ulcerative colitis, amebic dysentery)—in such instances the patient does not eat vitamin K-containing foods due to anorexia and their laxative-producing quality (exogenous sources) and absorption cannot occur due to destruction of mucous membrane (endogenous sources); (5) physiological hypoprothrombinemia of the newborn; (6) when succinylsulfathiazole (sulfasuxadine) or Sulfathaladine is administered for preoperative preparation in colonic surgery or in the treatment of various types of colitis; here the coliform bacteria are so greatly reduced that K_2 is not available.

The daily *requirement is not definitely known.* When *given by mouth,* bile is necessary for its absorption. Usually it is given intramuscularly; 2-methyl-1,4-naphthaquinone (menadione) is given in 2 to 4 mg. doses daily until the prothrombin time approaches normal.

Vitamin P (citrin) is said to control vascular permeability. It may be a factor in vitamin K.

This discussion does not mean that every surgical patient must have all of the vitamins mentioned. It does mean that in the preparation for surgery and in the aftercare these deficiencies must be corrected if present and anticipated if dietary requirements cannot be met. In succeeding chapters their specific uses *will be stressed; also* the daily water, salt, caloric, and protein requirements will be considered.

Trauma to tissue whether mechanical or through maceration or caused by the use of strong antiseptics (an antiseptic strong enough to be bactericidal may also be fatal to cells), will produce all the obstacles to wound healing previously mentioned. Death of tissue cells decreases local resistance and permits *infection* to occur, cellular debris acts as a *foreign body, the size of the wound* is increased, *blood supply* is interfered with, and the *general condition of the patient* is jeopardized because of absorption of toxic products.

Miscellaneous Causes.—

Temperature.—My associates and I studied wounds in guinea pigs which were observed at various temperatures. Excessive heat or cold delays healing. Brooks and Duncan found that heat hastened and cold delayed the inflammatory *reaction. Wounds heal best* in moderate tem-

peratures. Much has been written lately on the use of cold (cryotherapy) in the treatment of wounds (see Chapters 4, 5, and 6). It is wrong to assume that either heat or cold is indicated as a therapeutic measure in the presence of adequate blood supply. High fever also delays fibroplasia; this may be due to the increased temperature per se or its causes.

Acidosis and Alkalosis.—Wounds normally heal in a medium which is acid in reaction. Acidity favors vasodilation; however, when too acid (pH below 5) or too alkaline (pH above 7) vasoconstriction occurs. Slight acidity is said to favor vasodilatation, exudation, the action of autolytic enzymes, the more complete dissociation of oxygen, and local inhibition of bacterial growth.

Neoplasia.—Wounds made into malignant growths may heal but will do so with malignant cells. The process was studied in experimentally induced sarcoma. There was no localized increase in growths due to the wound healing stimulus which was superimposed on the already present proliferative stimuli within the malignant cells. There was no ingrowth of nonneoplastic tissue from the immediate vicinity about the sarcoma.

Diet.—Complete starvation does not alter the healing of a wound, although the lag period may be prolonged. After operation on the gastrointestinal tract, it is more important to attend to water balance and osmotic pressures than to food. The vitamins should be administered, especially thiamine chloride, ascorbic acid, and nicotinic acid. The velocity of fibroplasia and its proliferation is enhanced by high protein diets. Hypoproteinemia delays wound healing by decreasing osmotic pressure and permitting edema to occur. If this is corrected with acacia in the experimental animal, healing is normal. A general poor state of nutrition is more important in wound disruption than is hypoproteinemia. Carbohydrates are necessary also to secure good repair. Fat prolongs healing.

Age.—The lag period is longer in the aged, but once fibroplasia begins there is no difference. This means that the tensile strength of a wound after surgery is weak for a longer period of time. Wounds seem to heal faster in the young, and it has been said that the rate of healing is inversely proportional to the age. Surgery is often done on older persons and they must be mobilized early to prevent complications. Since the terms old and young are used in a relative manner, the surgeon should not withhold necessary surgery because of age alone. Anatomical incisions sutured with silk, linen, or cotton allow for early mobilization, and the delay in healing is usually due to other general factors already mentioned rather than age per se.

Allergy.—Allergy may produce a delayed healing or even premature absorption of catgut. Hopps found that hypersensitivity to catgut could be produced in rabbits and guinea pigs as shown by positive cutaneous reactions, positive reactions from implantations in the anterior chambers of the eye, and demonstration of humoral antibodies (precipitins, agglutinins, complement-fixing antibodies, and anaphylactins). There was an

In addition, it protects the body and, through glands, secretes important substances for body metabolism. It occurs in skin (stratified squamous epithelium), in the mucous membranes, and in the respiratory tract (pseudostratified epithelium). It is found in glands (breast) and glandular organs like liver and kidney (simple cuboidal epithelium). Epithelial tissue is perhaps the second best healing tissue; it will heal and replace itself, as we have seen in skin wounds. The epithelium which forms over an injured area, however, contains no sweat or sebaceous glands or hair follicles.*

Fig. 18.—X-ray photograph of a fractured femur, showing the formation of callus and the manner in which the continuity of the bone is reestablished, even though the reduction is not perfect.

3. Vascular tissue includes the blood corpuscles and the cells lining the blood vessels and lymphatics (endothelium). The blood corpuscles do not regenerate, although new corpuscles are constantly produced by a specialized organ, bone marrow, whose function it is to replace this tissue. The endothelial cells regenerate completely, permitting the preservation of vascular continuity after injury.

*The term *mesothelium* is applied to the lining of body cavities such as the pleura, peritoneum, and pericardium. These serous membranes are specialized loose connective tissue in a way. *Mesenchymal epithelium* is used to designate the lining of the subdural, subarachnoid, and perilymphatic spaces of the inner ear and the chambers of the eyeball. Joint cavities and bursae are lined by synovial membranes which contain epithelial cells and vary in morphology depending upon their underlying tissue—fibrous, areolar, and adipose. These simple squamous epithelial tissues which are mesodermal in origin heal readily.

4. Muscle tissue is highly specialized and does not readily regenerate itself. Striped muscle is mesodermal and unstriped mesenchymal in origin. The former has practically no power of regeneration; the latter cells retain some power of mitosis but regeneration is not seen after any major defect. If muscle is divided and sutured, it will join together, but not usually by muscle tissue. Surgeons will not cut across muscle, or suture it tightly, or include large amounts in the suture, because it heals with scar—not muscle tissue. In the abdominal wall the fascial coverings supply the tensile strength.

5. Nerve tissue is ectodermal. Animals have a certain number of nerve cells at birth (see Chapter 18)—some more, some less. These cells develop but do not increase in number. If the nerve cell is killed or injured, it never regenerates itself; it is gone forever. This is what happens to children with anterior poliomyelitis or infantile paralysis.

The more highly specialized the tissue, the less able it is to regenerate itself.

Repair as Seen in Specific Tissues

Bone.—

Bone develops late in embryonic life as a transformation of embryonic or adult connective tissue—after muscles, nerves, vessels, and many other organs are formed. Certain bones develop from connective tissue directly and are called membrane bones (intramembranous bone formation); others develop from cartilage and are called cartilage bones (endochondrial ossification). Spongy bone is first formed, and later it becomes compact through internal reconstruction. Membrane bones are seen in the face and the flat bones of the skull. These have a periosteum and two layers of compact bone, between which is the diploic cavity. Cartilage bones occur in the skeleton generally. The mandible is formed from Meckel's cartilage, which serves as a surface for the deposition of bone by connective tissue. The cartilage is later absorbed. Thus the lower jaw does not undergo endochondrial ossification. A long bone is composed of a diaphysis or shaft, an epiphysis or growing portion, and a metaphysis, which is adjacent to the epiphysis and is rich in blood supply. The metaphysis is important because here most infections occur and many new growths as well. It has a cortex made of compact bone and a medulla made of cancellous bone. The cortex is surrounded by periosteum, which, in the young, is composed of two layers—an outer fibrous one which carries vessels and nerves and an inner cellular layer which is filled with osteoblasts and has an osteogenetic function. The cancellous bone is lined by endosteum which is also osteogenetic. The compact bone is chiefly made of tricalcium phosphate, which lies betwen the meshes of interlacing collagenous fibers called *lamellae*. Some of these lamellae surround the haversian canals (Haversian lamellae). Within the canal are the artery and vein, connective tissue and fat cells, and some osteoblasts. Volkmann's canals also contain vessels but are not surrounded by concentric lamellae. Periosteal, interstitial, and endosteal lamellae are also seen as part of the meshwork, running in different directions. In the extremities the bone arteries run toward the elbow and away from the knee. Growth occurs at the epiphyseal ends, which are cartilaginous and ossify at various times in different bones, finally joining the shaft when growth is complete. The circumference of the bone grows from periosteum and endosteum. Some osteoblasts become enclosed in the matrix as bone cells and connect with each other through canaliculi.

When a bone is broken, a blood clot forms and fibrin is deposited There is an exudate and, in addition to the cells and collagenous material seen in superficial wounds, two special types of cells appear—*osteoblasts,*

which become osteocytes, and *osteoclasts.* The osteoblasts correspond to fibroblasts, but instead of forming collagen they form a soft substance known as *osteoid tissue.* This is laid down along the paths of blood vessels in trabeculae, at first transversely and later longitudinally, and serves to attract calcium salts.

The calcium phosphate which is deposited in bone apparently comes from adjacent bone rather than from the blood stream. Therefore, the administration of calcium by mouth influences bone formation only indirectly, for it must first be deposited in the storehouse of calcium (bones). These general principles are true of all injured tissues. *The cells which repair a particular kind of tissue come from neighboring tissues of like kind.* Such cells will usually appear in direct proportion to the adequacy of the blood supply and will *follow, not precede, the formation of the blood vessels. If inadequate,* granulation tissue will form and the defect will be healed by scar. If entirely absent, *repair cannot take place.*

Connective tissue may change to bone in adventitious sites in the connective tissue beneath the renal pelvis. If the epithelium of the urinary or gall bladder is implanted near dense connective tissue (in dogs), bone develops from the connective tissue (Bloom).

The osteoclasts correspond to macrophages and clean up the debris, permitting a re-establishment of the marrow cavity. The osteoid substance forms a bulblike mass around the broken ends of the bone known as a *callus.* In the early stages, the callus is soft, but later it becomes hard. The edges of the bone unite, forming new bone with a solid center. Scavenger cells called *osteoclasts* appear. They re-establish the marrow cavity of the bone. Bone may be laid down in connective tissue, as in the skull, or it may originate in cartilage, as in the long bones. Intermediary cartilage is mostly seen in the external portion of the bone. Drill hole observations reveal no intermediary cartilage. It is probably true that cartilage occurs in proportion to its need for temporary stabilization; that is, in incomplete fractures or a drill hole it is absent. In more complete injuries it is temporarily present. This hyaline cartilage undergoes degenerative changes when its usefulness is complete, disappears, and is replaced by bone. If the blood supply is poor, the continuity of the bone may be restored by fibrous tissue from surrounding structures or cartilage and may remain so. Thus we see that in healing, bone roughly retraces its formation and may stop at any stage, depending on its blood supply and other delays in repair previously enumerated. The skull heals by fibrous tissue only (thereby avoiding pressure on the brain by callus); the long bones, by connective tissue which is transformed into cartilage and then bone.

Intermediary cartilage degenerates due to the activity of mesenchymal cells and invading capillary loops. If such capillaries do not appear, the fracture may be healed by cartilage which is not replaced by bone. Dissolution of this cartilage is thought to be due to the action of blood vessel endothelium and "surrounding elements" which dissolve the interstitial substance in an unknown manner. Then the osteoid granulation tissue permeates the destroyed cartilage and changes it to bone through the action of the osteoblasts.

When a surgeon sets a bone, he must guard against the six factors previously described which delay healing.

Cartilage.—

Cartilage is a mesenchymal tissue developing from precartilage. It is made of homogenous, collagenous substance which is chemically a mixture of collagen, chondromucoid, chondroitin sulfuric acid, and albuminoid. In the many large spaces or lacunae are seen the cartilage cells (chondrocytes). These have been shown to contain glycogen. Cartilage grows by *interstitial* growth (production of more intercellular substance when the cells divide by mitosis) and by *appositional* growth (formation of new cartilage over the external surface). It is devoid of blood vessels. The nutritive fluid in the capillaries of the perichondrium must pass through the interstitial substance to reach the cells. A connective tissue envelope surrounds the cartilage—the perichondrium. Three types of cartilage exist: *hyalin cartilage*, which is found in the larynx, nose, trachea, bronchi, xiphoid cartilage, costal margins, and joints; *elastic cartilage*, which contains in its matrix yellow elastic fibers and is found in the external ear, auditory tube, epiglottis, and the small cartilages in the larynx; and *fibrocartilage*, which contains anastomosing bundles of fibers and is seen in the intervertebral discs, interpubic fibrocartilages, and in the sternoclavicular, acromioclavicular, and mandibular joints.

Cartilage heals slowly but completely. It is like bone in origin, being derived from mesenchymal tissue. It has no blood supply of its own and is nourished by surrounding tissues. It is a forerunner of bone. Due to its poor blood supply, inflammation and healing will be extremely slow. Cartilage has the ability to obtain nourishment from the surrounding tissue; hence it can be used in plastic surgery. It can be transplanted and will live. Repair takes place by a metaplasia of the loose connective tissue around the cartilage. Any connective tissue after injury may change to cartilage. Function may determine this in bone or cartilage. False joints in unreduced fractures may be lined by cartilage.

Intestines.—

The gastrointestinal canal develops from the foregut, midgut, and hindgut. It is composed of four layers, tunica mucosa, tela submucosa, tunica muscularis, and tunica adventitia (or serosa). The mucous membrane is laid down first from the mesenteron; later the connective tissue elements surround it. The esophagus and rectum do not have a serosa; they are surrounded by an adventitia of connective tissue. The blood supply comes from the mesentery and encircles the bowel, dipping into its layers closer to the mesentery in the small bowel and then large bowel, in which the vessels penetrate close to the antimesenteric border, almost surrounding the bowel wall on the outside. Gangene from distention is therefore rarely seen in the latter and commonly seen in the former.

The intestinal wall is composed of mucosa, submucosa, muscularis, and serosa. The submucous coat, which is found between the muscle and mucous layers, is the strongest coat in the intestine. This is the fibrous substance of which violin strings and surgical catgut are made. The serous coat is the quickest one to heal, but it will do so only when its cells approximate each other: that is, serosa to serosa. Therefore, in intestinal surgery the bowel wall is turned in. After one-half hour a deposit of fibrin occurs due to clotting of blood plasma; later a collagenous exudate forms and prevents leakage. If it were not for this, we could

not possibly do any intestinal surgery. Even the most delicate suturing would not prevent leakage and subsequent peritonitis were it not for the astounding ability of the serous coat to seal itself so rapidly and completely. This must be remembered in surgery on the esophagus or rectum which are devoid of serosa and therefore heal less readily. The inner coats are sutured first (the muscularis is of minor importance in repair) and then turned in. They heal by second intention because they slough or become infected. However, infection may be reduced by the use of succinylsulfathiazole or phthalylsulfathiazole (Sulfathaladine) preoperatively. (See Chapter 5.) The serous coat heals by granulation from the subserous connective tissue. This begins in twenty-four hours and is complete in about a week. The inverted serosa is absorbed. Food and water are withheld for about four days, so that the inner coats may

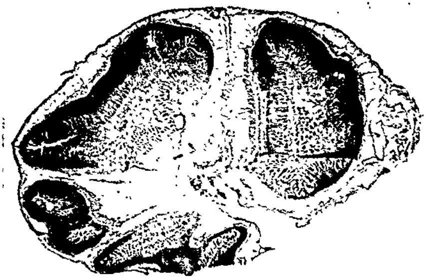

Fig. 19.—Healing of intestines (dog). Section was made on seventh day after suture of intact loops of bowel. Note large amount of fibrinous exudate. Organization has begun. The serous coat is undergoing absorption.

form healthy granulation tissue before being subjected to the stress of digestion. (Although with the use of the Levine and Hiller-Abbot tubes and suction, fluids may be allowed by mouth after twenty-four hours.) The mucous membrane is regenerated, including some of its glands.

Muscle.—

Skeletal muscles develop from mesodermic somites. Muscle tissue is highly specialized and has contractile power. Each muscle fiber has a sheath (sarcolemma), which surrounds the cytoplasm (sarcoplasm) and the peripherally placed nucleus. The sarcolemma is one micron thick. It is a structureless membrane derived either from the muscle cell or the connective tissue surrounding the muscle fibers. The myofibrils are arranged in fields (Cohnheim's areas), muscle columns, or sarcostyles. When viewed in cross section, muscles appear to be divided into bundles or fasciculi by connective tissue, which ultimately blends with the sarcolemma around the individual muscle fibers (internal perimysium or endomysium). This, in turn, is derived from the capsule of the muscle (external perimysium).

Muscle tissue may undergo hypertrophy but not hyperplasia. Therefore, muscle tissue, striped or unstriped, does not regenerate itself when destroyed. It therefore fills in with scar tissue derived from the external and internal perimysium. Striped muscle has almost no power of regeneration. Unstriped muscle cells do have the power of mitosis. However, regeneration is not noted except in very small wounds.

Tendons.—

Tendons consist of very dense connective tissue with collagenous fibrils, bound into bundles in a matrix containing tendomucoid. Very little elastic tissue is present. The bundles or fasciculi are separated by septa. Their peritendineum surrounds the tendon and gives rise to these septa. Many tendons have sheaths surrounding the mesotendineum which carries the blood supply. Tendons are attached to muscles and bone. The collagenous bundles of the external perimysium pass directly over into those

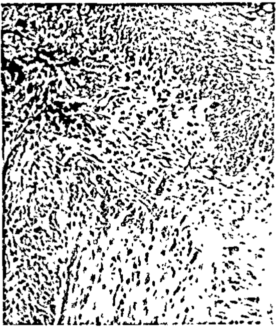

Fig. 20.—Repair of muscle (rabbit's tongue). Muscle fibers have been replaced by fibrous tissue.

of the tendon; the sarcolemma covering the rounded, cone shaped ends of the muscle fiber is fused with the ends of the collagenous bundles. Tendons are attached to bone through the periosteum. At such sites may be found Sharpey's fibers which are also collagenous bundles of varying thickness passing through the systems of lamellae in different directions.

Tendons heal very quickly and completely and may be divided, lengthened, shortened, or transplanted. They are mesenchymal tissue and heal as well as connective tissue. Silk is used as the suture material and the sheath is closed. Early motion was formerly advocated to prevent adhesions. This was a fallacy because repair takes place as in other related tissues. Softening occurs immediately after suturing, and stitches will pull out unless fibroplasia is well established (fourteen days). Usually *three to four weeks in splints is necessary for complete repair.*

Blood Vessels.—

Blood vessels are composed of three principal layers: *tunica intima*, which includes the endothelium and, generally, an underlying elastic membrane; the *tunica media*, which is primarily a layer of circular smooth muscle fibers (relatively thicker in the arterioles and thinner in the larger arteries, where elastic tissue is more common); *tunica externa*, or *adventitia*, which is chiefly connective tissue and carries the blood supply (vasa vasorum) and the nerve supply. Veins are like arteries except that their walls are thinner and they have valves. *The external coat of veins is better developed* and the muscle coats contain more longitudinal muscle fibers.

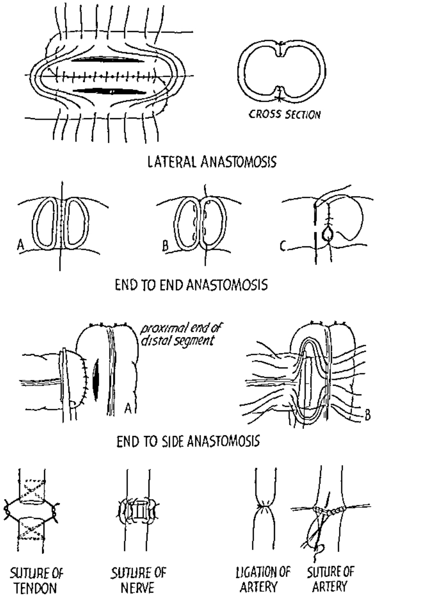

Fig. 21.—Diagram illustrating methods of repairing intestine, tendon, nerve, and artery. The intestinal suture is placed so that the serous coat will be inverted, approximating serosa to serosa. The method shown for tendon is designed to catch the longitudinal fibers, so that the ends will remain in approximation. The nerve is sutured with *stitches through the epineurium.* In the repair of blood vessels it is important that intima be approximated to intima. This is accomplished when simple ligation is done or when vessels are sutured by an eversion running mattress suture. At times this is not possible, as in the production of an artificial ductus by anastomosis of the pulmonary artery and aorta. *In this instance the posterior suture line is a continuous over* and over. Some surgeons use an eversion mattress suture interrupted followed by a continuous over-and-over stitch. This type is employed in anastomosis of the aorta following the excision of a coarctation. However, good results are obtained by a continuous over-and-over stitch.

Blood vessels are composed of intima (endothelium), media (muscle), and adventitia (connective tissue). If the lining of a vessel is roughened, a clot (thrombus) will form. In wounds of blood vessels this takes place and is nature's way of arresting hemorrhage. If the surgeon ligates a vessel he approximates intima to intima, and healing with regeneration occurs. Suturing of vessels is now a common practice. Should it be necessary, the finest silk (00000 on atraumatic or swadged on needle) *should be employed and the intima should be sutured to intima. Indications* and conditions for successful arterial suture are as follows: The vessel should be large with few collaterals; it should not be diseased (arteriosclerotic); the wound should not be infected; the divided ends cannot be too far apart, producing tension on the suture line. Best results are seen when the vessel is only partially divided (up to 50 per cent). (See Chapter 17.)

Nerve Tissue.—

Nerve tissue is derived from ectoderm and its unit is the neuron. The neuron is composed of the nerve cell, its dendrites, the axis-cylinder (which may be surrounded by myelin), and the neurolemma or sheath. The axis-cylinder in myelinated nerves is centrally placed. The nerve sheath or neurolemma (sheath of Schwann) shows at frequent intervals annular constrictions—the so called nodes of Ranvier. This structure is probably not connective tissue but a membrane similar to the sarcolemma (q.v.). Nuclei occur in the neurolemma midway between these nodes. Around the peripheral nerves is a connective tissue sheath (epineurim). Within this layer nerve cords are grouped and held together by the perineurium, which in turn divides the neurons into groups by an inward prolongation (endoneurium) or "sheath of Henle." Thus a nerve on cut section is seen to have a pattern which should be matched when cut nerves are sutured.

A nerve cell (neuron) is composed of a cell body and an axis-cylinder. In so-called myelinated nerves the axis-cylinder is surrounded by myelin and a neurolemma, or sheath of Schwann. (Myelinated nerves include motor nerves and sensory nerves peripheral to the posterior ganglia.) If the axis-cylinder is not myelinated and surrounded by neurolemma, it will not regenerate.

Division of nerve fibers in the spinal cord is not followed by regeneration except in very young experimental animals. Motor nerves do not assume their myelin sheaths until they leave the cord. Sensory nerves have no myelin central to the spinal ganglia. Although myelin is formed in the medulla spinalis, the nerve fibers in the cord have no neurolemma and this is probably responsible for their failure to regenerate.

We have said that a nerve cell will not regenerate itself. If a nerve fiber is injured, its sheath will repair itself as do other tissues, but the axis-cylinder will form only by new growth from the cell body. After the axis-cylinder is cut, it degenerates and breaks down into granules (Wallerian degeneration). This process extends peripherally to the end of the nerve and centrally to the next node of Ranvier. The myelin sheath disintegrates into fatlike droplets which are finally absorbed. The nuclei of the Schwann cells multiply and line up in rows parallel to the axis-cylinder. The cell body may show Nissl's granules. Although

the surgeon does not suture each neurolemma, he does approximate them when he sutures the epineurium of a nerve. Then the new nerve fiber grows down the empty sheath.

Advantage is taken of this fact in extensive injury of nerve. For example, in the repair of the facial nerve an empty sheath is inserted between the cut ends of the nerve. This sheath is obtained by dividing the anterior cutaneous nerve of the thigh, allowing the axis cylinder to degenerate and then removing a portion of the distal end of the nerve.

The only thing that heals by intention is the sheath (that is, any type of intention, be it first or second); the axis-cylinder grows down this sheath if the cell body is uninjured. To re-establish function in the nerve, the axis-cylinder must grow all the way down. If it is a long nerve (as the sciatic), it may take a year for it to heal and for function to be restored. A complex nerve (such as the ulnar) is less apt to regenerate completely than a simple nerve (such as the radial), and an almost purely motor or sensory nerve regenerates better than a mixed nerve. Should the regeneration of the axis-cylinder be interfered with by scar *tissue, the nerve will curl at the end, forming a painful bulblike swelling* called a *neuroma.*

thelial cells have more bacteria and the converse is true. These cells engulf but do not always destroy microorganisms. Bacteria have been found in the lining of the stomach, but in most cases they are destroyed by the hydrochloric acid in the gastric juice. Practically every tissue in the body, then, may contain bacteria, but their mere presence does not constitute an infection or a disease. Also, as in the soil, very few tissues contain only one type of germ and if infection occurs many strains may be responsible. It is the natural or acquired immunity to these organisms that keeps us in a healthy state (q.v.).

IMMUNITY

Immunity may be defined as a state in which the body is resistant to a specific bacterial or virus invasion. The word resistance is a relative term and implies a general strength against bacteria. It is that inherent quality of healthy tissue which makes it an unfavorable site for bacterial growth. Various kinds of immunity are known: (1) *local* (in individual tissues and their cells); *general* (through the antibodies of the blood; (2) *natural* (inborn); *acquired* (as a result of experience with the disease, of maturation, or of vaccination; (3) *active* (produced by the individual's own forces); *passive* (conveyed by injection of immune sera).

Local immunity is applied to the resistance of the tissue cells at the site of the infection. There is no doubt that local tissue immunity is very important, if not the most important, part of our resistance to disease.

Walsh and Cannon found that they could immunize rabbits against pneumococci by local vaccination with formaldehyde-killer or autolyzed pneumococci. Since there were no demonstrable antibodies in the blood stream, they considered the immunity to be entirely local.

Wood has described three histologic zones in pneumonia: an outer zone filled with edema fluid in the alveoli; few leucocytes, and many pneumococci which multiply here and spread the lesion. Inside this zone the alveoli contain many leucocytes and bacteria. A feature here was that there were less bacteria and more leucocytes the more central the area. Polymorphonuclears were ingesting the organisms. The central zone is characterized by consolidation due to fibrin and leucocytes, no microorganisms, and, in the older portion, macrophagic resolution.

The mechanism of the therapeutic arrest of pneumonia by the use of immune serum is due to agglutination and immobilization of the pneumococci by alveolar adhesion. This may be due to specific epithelial opsonins very much like so called "endothelial opsonins."

Mesothelial-lined cavities owe some of their resistance to serous fluids. These not only dilute toxins but contain freely floating cells which are macrophages and correspond to polyblasts in inflammatory exudates. Desquamated epithelial cells may turn into fibroblasts. Small lymphocytes may become macrophages. These cells with their primitive ability to differentiate aid in establishing a high degree of local resistance.

The intact skin has always been thought to be an impermeable barrier to bacteria. This is probably true, but recent studies have shown that virus (lymphocytic choriomeningitis) may penetrate the intact skin of guinea pigs. Thus we have experimental confirmation for our practice of giving antirabic vaccines to persons who have been licked or otherwise contaminated by the saliva of rabid animals or patients (see Chapter 7).

Chapter 4

BACTERIAL INVASION—THE REACTIONS OF TISSUES AND THE BODY AS A WHOLE TO BACTERIAL INJURY

Bacteria may be found almost everywhere.

Spores are found even in the stratosphere, where the ordinary flora of the air are not encountered. However, spore-bearing bacteria, when taken up into the stratosphere from earth, survive. Organisms are said to live in symbiosis (cannot exist independently), mutualism (both are benefited), and mensolism (one is benefited, the other unaffected).

The physician must be constantly alert to the danger they present. Microorganisms are not all harmful. *Saprophytes* are those bacteria which live on dead or decaying matter; *parasites* are those which thrive on living matter. The saprophytes cause certain ferments to form in the intestinal tract and probably aid in the digestion of food; coliform bacteria aid in the formation of vitamin K_2 in the colon. Dirt and soil contain virulent anaerobes; various species of bacteria, fungi, actinomycetes, and genera of algae; all types of protozoa, nematodes, worms, insects, and viruses. These microbes carry out their activities in the variegated fauna and flora which is usually present in soil. They may act in symbiosis, aiding one another in useful functions (fixation of atmospheric nitrogen, production of nitrite from ammonia, decomposition of proteins or cellulose), or they may inhibit each other by the production of antibiotic substances (penicillin, streptomycin, aureomycin, tyrothrycin, gramicidin). Virulent anaerobes make dirty wounds dangerous. Experimental animals living in an aseptic environment do not thrive very well. There are germs all through the body, particularly in cavities or ducts which communicate with the outside, such as the mouth (around teeth and tonsils), the nose, the vagina, the rectum, and the urethra. The deep layers of the skin (glands), muscles, liver, kidney, and other parenchymatous organs are also inhabited by bacteria.

These bacteria are mostly gas-producing anaerobes which are harmless when injested into experimental animals. However, they may become virulent when contaminated with ''transient'' organisms. The gastrointestinal tract of the newborn is free from bacteria for the first five to ten hours. This was determined by us in operations for imperforate anus. However, we have operated upon infants within the first five hours of life, opened the blind hind-gut, and found coliform organisms.

The only tissues which are supposedly free from bacteria are the brain and spinal cord, heart muscle, cartilage, cortical bone, tendon, and the eye chambers. Those organs having an abundance of reticulo-endo-

It is due to the presence of phagocytic cells, such as tissue wandering cells, macrophages, and all reticulo-endothelial cells, as well as to migration of leucocytes and to chemical substances (leucoprotease, lymphoprotease, erepsin-like substances) elaborated by the leucocytes which have the power of inhibiting the growth of bacteria or rendering them more susceptible to phagocytic destruction. Local immunity is also aided by lymphatic fibrin plugs and immune bodies (opsonins). This explains why certain contaminated tissues may heal by first intention (vagina, rectum, mouth), although when traumatized severely they do not always do so. If strong antiseptics are employed, local resistance is so reduced that a wound is considered as infected even if seen early. Some tissues such as the pleura and peritoneum have by nature a high degree of immunity. Others possess this because of good blood supply (face). One may contaminate a clean wound after eight or ten days with staphylococci without producing a general infection (local immunity). Healing by second intention takes place only after local immunity has been established.

General immunity is also extremely important in our defensive mechanism.

Pfeiffer was one of the first to show the ability of an immune animal to destroy bacteria, as distinguished from the power to neutralize their soluble toxins which had been shown by Ehrlich. When cholera spirella were injected into the peritoneal cavity of cholera-immune guinea pigs, the microorganisms swelled, became granular, and under went solution. When the bacteria were injected into a normal animal along with a sufficient dose of cholera-immune serum, the same effect was produced. However, in the unprotected animal death invariably resulted.

It has long been known that virus diseases especially infantile paralysis, seem to affect well-nourished children. Recent experiments show that the rate of intradermal spread of virus varies inversely with the amountof interstitial water: increased amounts of interstitial fluid reduce the rate of spread and dehydration increases the rate and area. Depriving rabbits of food was found to increase interstitial fluid. If they were given plenty of water, their resistance to vaccine virus was increased.

It is chiefly humoral and is thought to be due to chemical substances in the blood known as antibodies. Depending upon their mode of attacking toxins or bacteria, they are called agglutinins, precipitins, bacteriolysins, opsonins, alexins, or antitoxins.

These protective antibodies are newly formed chemical substances which are synthesized within the cell Precipitins are normal serum globulins synthesized intracellularly and altered by the "templating" action of the absorbed antigen. This antigenic template is synthesized from intracellular protein reserves. Thus ample *protein reserve* means an ample supply of antibodies in most instances. Normal antitoxic resistance to diphtheria toxin is quadrupled on a high protein diet.

Formerly there were two schools of thought concerning immunity. The "cellular group," headed by Metchnikoff, thought that local cells played the most important role; the "humoral group," led by Ehrlich, believed that antibodies were more important. Today we know that both play important roles in defense reactions.

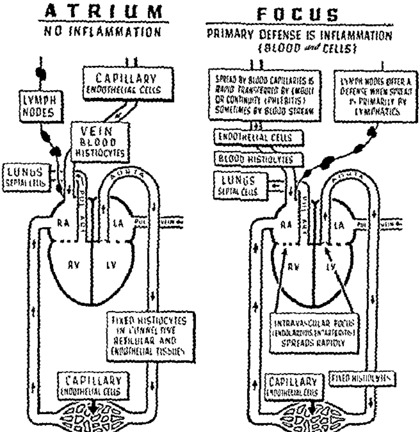

Fig. 22.—Diagram illustrating the dissemination of infection from an *atrium* and from a *focus* of infection. Note that there is *no inflammation* about an atrium so that there is direct access to the lymph or blood capillary. The lymph method of dissemination offers an early line of defense in the *lymph nodes* and the endothelial cells of the tubular lymphatics. Ultimately, bacteria gain entrance to the venous system through the right lymphatic duct or the thoracic duct on the left. From here bacteria may be carried through the right atrium, right ventricle pulmonary artery to the lungs. Here the septal cells remove some of the bacteria. The rest find their way through the pulmonary vein to the left atrium, left ventricle, and the arterial system. Here the bacteria are removed by the fixed histiocytes in connective, reticular, and endothelial tissues. In addition, endothelial cells in the capillaries as well as wandering histiocytes in the blood stream aid in the elimination of bacteria from the circulating blood.

Should bacteria gain entrance through the blood capillaries, dissemination would be more rapid. Although the endothelial cells of the capillaries and the blood histiocytes attempt to remove entering bacteria, the veins carry the blood directly to the heart; then the circulation and removal of bacteria from the blood stream is the same as discussed above In either event bacteria are removed by the reticulo-endothelial system so that actual growth of the microorganisms probably does not take place within the blood stream unless the reticulo-endothelial system is completely filled or blocked.

This is usually a terminal event in the human being A blockade of the reticulo-endothelial system can be produced experimentally with dyes. Such animals develop a fatal bacteremia quickly after the injection of virulent organisms.

A *focus* of infection implies an inflammation. Here a primary defense is set up composed of blood and cells (inflammation) as described in the text. From this focus, bacteria may spread in two ways: (1) by blood capillaries and (2) by the lymphatics. The spread by blood capillaries may be rapid and may be transferred to distant areas by emboli or to neighboring regions by continuity (phlebitis). Sometimes the spread occurs by the blood stream itself in late cases. Should the focus be within the blood vessel, as in *endocarditis* or *endarteritis*, the *dissemination of bacteria is continuous* and severe. Lymph nodes offer a defense to the spread from a primary focus by way of *the lymphatics and, therefore, are more apt to halt the onset of bacteriemia.* In either instance, once bacteria reach the blood stream, the method of removal of microorganisms *is the same as described under atrium.*

These concepts explain variations in temperature and leucocyte counts as well as the *finding of positive and negative blood cultures in the presence of a bacteriemia.*

Active immunity is the same as *acquired immunity* and is the result of experience with the disease or vaccines; in other words, the patient fights his own battle with his own blood and cells. Passive immunity is conferred upon the patient by the use of immunizing serum, such as diphtheria antitoxin or tetanus antitoxin. Absolute immunity is rare and practically unknown in man, although there are very few diseases to which he has no immunity (for example, glanders). Dogs are supposed to have an absolute immunity to leprosy.

VACCINES AND IMMUNIZING SERA

Vaccines are substances made from attenuated or killed bacteria or their toxins. They are injected to produce active immunity, and they are used chiefly to prevent disease, but, in some instances, they are used to raise resistance in chronic diseases. Examples of the former are *typhoid fever and smallpox vaccines. Examples of the latter are staphylococcus* and pertussis vaccines.

The Kruger method of producing pertussis vaccine is a mechanical grinding process. Vaccines may also be made by ultraviolet irradiation. Toxoids are made by the addition of formalin to bacterial toxins and then incubating the mixture for thirty days. In addition, adjuvant substances such as alum may be added or the vaccine (in diphtheria and tetanus) may be included.

Vaccines may be either *autogenous* or *stock*. The autogenous are made from the patient's own pus; the stock, from laboratory cultures.

Immunizing serum is derived from animals that have been made actively immune to the disease by repeated injections of the organism. Such animals produce antibodies against the disease until they are immune. Their blood is then drawn and the serum is injected into the patient, thereby transplanting these immunizing bodies. This confers on the patient a passive immunity. Human immune serum is used in scarlet fever. Placental extract is rich in immune globulin and is used to prevent measles as well as other diseases.

Anaphylaxis.—Patients who have received injections of serum of any kind are rendered susceptible to the protein and, when given a second dose, may develop severe symptoms resembling shock. These may be so severe as *to cause death. If a local necrosis occurs at the site of the in*jection, it is known as the Arthus phenomenon; if general symptoms occur, the condition is called *anaphylaxis* or *anaphylactic* shock. If the symptoms develop only after eight or ten days, they are mild and consist of fever, lymphadenopathy, joint pains, and hives. This is known as "serum sickness"

(*Ana*, against; *phylaxis*, protection.) Besredka believed that anaphylactic shock does not occur under anesthesia because of the depressed sensitivity of nerve cells. Auer and Lewis believed that anaphylaxis is due to spasm of the bronchioles and is not of central origin. We have observed this bronchiolar spasm in our experiments. Dale thought it due to histamine. My colleagues and I have been able to produce anaphylac-

Immunity may be natural or acquired. An example of the former is the resistance which some individuals have to particular diseases as result of racial or hereditary factors, such as the resistance of natives of the tropics to yellow fever and the lack of resistance of the American Indian and Negro to tuberculosis. This is perhaps only partially hereditary. Experience with the disease early in life, survival of the fittest, and the inherited environment all play a role. Acquired immunity is the immunity that occurs as a result of experience with the disease, either in its active form or in a mild form produced by vaccines. Examples such as scarlet fever and diphtheria immunity may be cited. Some believe the rarity of childhood diseases in adults that have not previously had them is due to a mature immunological panel (see Chapter 10).

Experiments tend to show a sudden and great increase in prenatal immunity at the time of birth. We have found that the newborn stands surgery well and his microbic resistance is equal to that of older groups provided water and food balance are maintained.

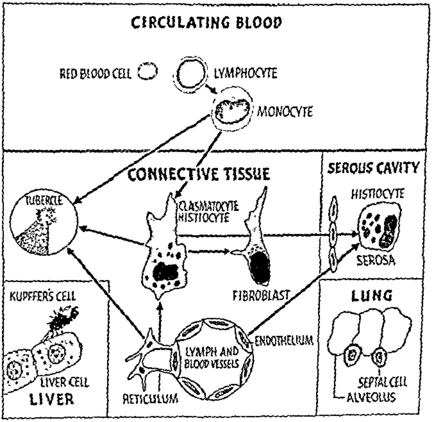

Fig. 23.—The reticulo-endothelial system. (After Gay: J. A. M. A. 97: 1193, 1931.) The principal sites of the cells and their possible derivations are indicated. The fibroblast only forms collagen and does not give rise to other cells. The epithelioid cells around the tubercle may be one source of fibroblasts. Most cells of the body may become phagocytic and in this sense are part of the reticulo-endothelial system. The reticulo-endothelial cells or histiocytes are usually divided into those which are fixed and those which are wandering. The fixed varieties are found in connective tissues, reticular tissues in the spleen, lymph nodes, and bone marrow, endothelium everywhere, lining of blood sinuses, "Kupfer cells" of the liver and especially endothelium of the spleen, bone marrow, adrenal and pituitary, and microglia. The wandering histiocytes are found in the tissues and in the blood stream. The latter may be of extraneous origin or the monocytes.

Local Effects of Infection.—*Inflammation* is the reaction of tissues to injury. The injury may be due either to simple mechanical trauma or to bacterial invasion. In either case, the tissue reaction to this insult, which is mechanical and cellular, denotes its presence. There are infections that are so overwhelming that the patient has very little reaction; fortunately this condition is rare. If the infection is due to a certain specific organism calling forth a characteristic reaction, it is known as a *specific infection* (for example, tuberculosis of the adult type). This means that the body will react to that particular organism in a certain manner. If the infection is produced by various organisms calling forth no specific type of reaction, it is said to be a *nonspecific infection* and is just like an irritation produced by trauma. The type of bacterial invasion is recognized by the defense reaction it excites, as well as by finding and culturing the *organism which is rarely of one type or strain. The concept of* specificity is probably inaccurate (see page 73).

When an inflammation occurs, *active hyperemia* is first noted due to the dilated capillaries carrying more blood and cells to the part. This occurs in response to any form of trauma and initiates the body's defense against it. Then *exudation* takes place. At first plasma, then after a few hours blood cells, go out into the field of the infection. This is due to increased capillary permeability in the dilated vessels at the site of infection. The loss of plasma prevents reabsorption of toxins because the osmotic pressure in the tissue spaces becomes greater than that in the vessels. Absorption can then only take place through the lymphatics. The lymphatic vessels, in turn, are occluded as intercellular pressure becomes increased, and within twenty-four hours, due to endothelial injury by the bacterial exotoxin, thrombosis and fibrin deposits are present in the lymphatics. Within forty-eight hours stasis occurs within the lumen of the blood capillaries. This is due to the loss of plasma and the packing of the capillaries with cells. After the fourth day thrombi appear in the blood capillaries also.

Thorsness and Higgins injected 10 c.c. of an 8 per cent solution of aleuronat subcutaneously into rabbits. Graphite was then injected on the fifth day. At autopsy none was found in the enlarged regional nodes. Sections of the walls of the abscess showed a network of fibrin from the first day, which began to break up by the eighth day. After this time (about the sixteenth day) graphite began to go through. Vitally stained macrophages (trypan blue) became evident by the second day and completely surrounded the abscess by the fifth day. Soluble substances such as phenolphthalein and epinephrine were well absorbed around the abscess, but in the abscess, after the fourth to sixth day, very little was absorbed (due to blockage of blood capillaries). This capillary blockage occurs later due to the fact that the neutrophiles reached their height by the second day; after this they decreased and the mononuclears (large lymphocytes, monocytes, histiocytes) increased, reaching a maximum after the fifth day. The influx of the polyblasts from the blood and surrounding tissues helped to block the capillaries.

tic shock in guinea pigs under ether anesthesia, although we have never seen it occur in human beings under anesthesia. Quill reports a single human case and many laboratory experiments to show that either does not protect against anaphylaxis. Many theories have been advanced to explain anaphylaxis:

1. A lysate is elaborated by the tissues after the first dose. A second injection causes a reaction due to excess lysate, which releases toxic fractions of protein.

2. The union of too much antigen with too little antibody. The latter is incapable of destroying the former but is capable of converting the inert protein into one which stimulates smooth muscle and acts like a poisonous substance, as does partially digested protein when given parenterally. This zone of incomplete immunity, whether on its way up or down, is the danger zone.

3. The resistance curve reaches its height in about eight days and then declines. If given during the ascent of the curve, the second dose of serum causes no reaction; if given during the descent, it causes anaphylaxis.

4. Moon believes the physiological disturbances are comparable to those which occur in peptone shock. *The reaction is cellular rather than humoral; the meeting of antigen and antibody within the cells irritates and injures them.* The capillary endothelium is the chief point of injury. The loss of tonus makes the capillaries become more permeable, and plasma is lost.

5. Perhaps the Arthus phenomenon is due to the local increase in capillary permeability resulting from the previous injection of protein.

6. Eclampsia has been ascribed to heterologization of placental protein and also to maternal isolysins formed against paternal Rh agglutinogens in fetal blood.

7. Bronchiolar spasm gives rise to anoxic anoxemia which may cause increased permeability of capillaries, loss of plasma, compensatory vasoconstriction, more loss of plasma and fluid, hemoconcentration, stagnant anoxemia, and shock. If this is true, oxygen and plasma would be of great help.

Individuals may be sensitive to proteins other than those in sera, such as pollen of plants, horse dander, certain proteins in foods, or bacteria and fungi. The latter may manifest themselves as local or distant reactions; "-id" allergy (tuberculid, epidermophytid) may remain until the primary site is cured. Even crystalloids and drugs may produce reactions (aspirin, arsenicals, etc.). Such sensitiveness is called *allergy* (literally, "other work"). It is therefore necessary to inquire of a patient, before giving serum of any sort, whether he has an allergy (as evidenced by asthma, eczema, migraine, hay fever, hives, or sensitivity to horses, and whether he has had serum before. When it becomes necessary to give serum under any of these conditions, it should be administered in small divided doses to prevent any serious reaction. Should a reaction occur, adrenalin and the nitrites are perhaps the best drugs to use. In addition, oxygen and plasma, if available, may help.

EFFECTS OF BACTERIAL INVASION

Contamination implies the presence of bacteria. **Infection** means not only the presence of bacteria but their rapid growth and destruction of tissue as well. Saprophytic infection may be midway between, implying the growth of the organism without invasion and destruction of tissue. Most microorganisms depend upon the destruction of tissue to exist and multiply.

capillaries begins to form but is destroyed by the bacterial toxins until a new granulation tissue creates an environment which is unfavorable for bacterial growth and invasion (local immunity). The thrombi in small vessels occur before granulation tissue is formed and remain until it is formed without being destroyed; then new capillary loops appear and the thrombi retract and become absorbed. However, by this time local immunity is established and surgical intervention or spontaneous evacuation of pus occurs. If pus is not evacuated, the granulation tissue behaves as it always does; that is, it cicatrizes and forms a scar. This scar forms a connective tissue wall which surrounds the cavity of pus, giving rise to an inflammatory cyst. It becomes a cyst because the pus becomes sterile and undergoes liquefaction.

The destruction of tissue at the site of an infection is not all due to bacteria. Autolysis occurs as a result of trypsin and pepsinlike enzymes which are liberated by dying cells. Heterolysis results from three enzymes. Leucoprotease is said to be produced by polymorphonuclear leucocytes and digests protein in an alkaline medium. Lymphoprotease is a product of the lymphocytes. It digests protein in an acid medium. Erepsin-like substance is also a product of the granular leucocytes and is said to act on proteoses. These enzymes are created by the cells to remove dead tissue and digest unhealthy tissue and thereby facilitate the spontaneous evacuation of an abscess. They may act within the polymorphonuclear leucocyte, thereby permitting the digestion of cellular debris and bacteria which they have engulfed. An antienzyme exists in the blood serum inhibiting the action of enzymes. Heterolysis does not occur, therefore, in untraumatized tissues.

Since bacteria thrive on the products of proteolysis, it would seem that this enzymic action is helpful to the invading microorganisms. It is also known that such products of proteolysis contain antisulfonamide factors (para-aminobenzoic acid). The more leucocytes, the more enzymic action. Since the enzymes do not affect healthy tissue, they simply clear the area of unhealthy cells, permitting the leucocytes to act and probably making bacteria more vulnerable for such action. In fact, certain enzymes are now being used (experimentally) to aid in the annihilation of bacteria (see Chapter 5). Since the leucoproteases do not affect untraumatized tissue, they do not in any way interfere with the process of localization. Sulfonamides could not enter and are not needed in such an area (see Chapter 5).

On the other hand, if the individual is weak, the infection is disseminated and may result in an overwhelming bacteriemia.

Different clinical types of infection are classified according to their length of duration as (1) *acute*, (2) *subacute*, and (3) *chronic*.

Harvey and Hamilton proved an invariable sequence of events in response to the entrance of foreign material into the body: first there appeared polymorphonuclears, followed by monocytes, and in time by lymphocytes. There is a chemotaxis which calls cells to a focus but not special kinds of cells. This depends on acuteness or chronicity, local tissue destruction, and duration of stimulus rather than on a specific reaction of the tissues to different types of stimuli. This is well exemplified in bone infections where an acute tuberculous infection may resemble that of the pyogenic organisms and a chronic staphylococcic type of infection (Brodie's abscess) may mimic tuberculosis.

Acute infections arise and develop rapidly. They are usually caused by a single successful invasion of the organisms and may be severe. The blood stream may be continually or continuously flooded with bacteria. They are either overcome by the patient in a relatively short time or cause death. *Subacute* infections are never severe and yet may produce

As a result of these processes infection is walled off. Experiments have shown that crystalloids injected into the infected area of an experimental animal are not absorbed. When a colloid such as India ink is injected into the center of an abscess it is not found in the neighboring lymph nodes even after the second day because the lymphatics are occluded, preventing the absorption of colloids. The ink remains within the abscess. This is the process seen in the localized infection and is usually associated with staphylococcus invasion (q.v.). In the more severe streptococcic infections these localizing factors are not seen and there results widespread destruction of tissue, with systemic absorption (see Chapter 5). In the center of this area of activity there is destruction of tissue.

Tissue cells are killed by the action of bacterial toxins. This destruction of tissue, or *necrosis*, will continue as long as the bacteria proliferate and invade the tissues. In pimples the area is small; in boils and carbuncles, much larger. In diffuse infections it is extremely large. Within the area of destruction many cells are found; these are the polymorphonuclear leucocytes; later macrophages and monocytes appear. Accumulations of large numbers of cells finally fill the cavity. This process is known as *suppuration* (formation of pus).

As we have learned in Chapter 1, surgeons during the Middle Ages spoke of "laudable pus." Properly interpreted, pus is laudable and indispensable in the control of severe infection. If a patient is not overwhelmed by an infection in two or three days, the reaction which we have described occurs. Surgeons have always known this and have therefore preferred wounds which suppurated (staphylococcus?) to those which did not (streptococcus). The practice even existed of inducing suppuration by setons. This, of course, is no longer condoned. Pus is a fluid made of tissue debris, leucocytes, and their enzymes. These are nature's agents for the destruction of bacteria, the digestion and removal of necrotic material, and the irrigation of the area. This is the rationale for the modern treatment of infected wounds. Pus under pressure favors absorption and the separation of septic emboli. Therefore, incision after localization is all that is necessary. Pus will loosen and digest necrotic tissue. Anything interfering with this process thwarts the mechanism; therefore, irrigations, packing, and strong antiseptics should not be used. In fact, *rest* to the part and *avoidance of trauma* through massage and active motion will delimit lymphatic absorption. Therefore the treatment necessary in any infection is rest plus drainage after localization, with general supportive treatment (water balance, blood transfusion, etc.) and perhaps sulfonamides or penicillin in streptococcic and sulfadiazine in pneumococcic infection.

If the individual is strong and his fighting forces are active, *local immunity* occurs; then healing takes place by second intention.

We have previously shown (Chapter 3) that the granulation tissue in an infected area is like that between the edges of any wound healing by second intention. Let us examine a contused wound made by a blunt force. There would be very little bleeding, for the crushing force stimulates early thrombosis in the vessels. Then the sequence is hyperemia, exudation, granulation tissue, vascularization, and repair. The bacterial infection causes destruction of tissue cells and the process is the same. Thrombi may appear in the capillaries within forty-five minutes. Granulation tissue along with new

The vascular response to an irritant may be completely absent in rabbits with staphylococcic septicemia. This is probably due to a diminished circulation in the small blood vessels of the skin due to vasoconstriction which does not permit leucocytes or dyes to reach the area. The same phenomenon appears in shock from hemorrhage or other causes.

If no leucopenia exists, the foregoing explanation may mean that leucocytes are fighting the bacteriemia in more vital areas than the skin. Indeed they may exist in the peritoneal cavity, for example, in such large numbers as to produce a relative leucopenia.

Patients stand surgery poorly in the presence of severe septicemia. Therefore, operative intervention is limited to the relief of the focus of infection, and the operative procedure should always be as innocuous as possible. Children with measles or scarlet fever may develop a gangrenous stomatitis from the extraction of a tooth. However, the important fact is the general condition of the patient rather than the septicemia. If careful attention is given to water and electrolyte balance, proteins and carbohydrates, blood and plasma, as well as to vitamins, surgery can be made safe in the presence of a bacteriemia. Formerly typhoid fever was treated by starvation diets. Such patients did not react favorably to surgery. Now they are well fed and surgery is safe. It is therefore not so much the presence of bacteria as it is their interference *with vital functions that delays or prevents a proper inflammatory response to injury.*

Treatment of local foci by surgery in the presence of septicemia should be preceded by attention to the two factors which interfere with local inflammatory reactions; namely, the general condition of the patient as to nutrition and water balance and the showers of bacteria in the blood stream. Fortunately both are amenable to treatment, the former as indicated above, the latter by antibiotics (penicillin, streptomycin, aureomycin), and chemotherapeutic agents (sulfonamides).

In addition to redness there is heat (calor). Physicians speak of "hot" infections as opposed to the "cold" ones seen in tuberculosis. An infected area actually feels hot. However, if we take the patient's temperature (per rectum) and then take the temperature at the center of the infected area, it is about the same. The field of infection is hot, but *the temperature is the temperature of the blood. The blood surges* through this field so rapidly and in such quantity that the surface temperature is much higher than that of other skin areas; therefore, by contrast, it feels and is hot.

The third symptom is pain (dolor). The patient is in pain, because the tissues are stretched by the exudate, and the tension produced by this pressure, plus the effect of bacterial toxins, stimulates or injures the nerve endings, making the infection painful. The infected area is swollen (tumor). Swelling is present because more blood vessels are required to bring more blood into the part; but there is another reason—exudation. Blood cells, plasma, serum, tissue wandering cells, and lymph accumulate in the tissues. When suppuration occurs, the swelling is due also, in part, to pus formation. If the infection is deep or internal, *pain* plus the general symptoms and signs of infection lead to a proper diagnosis and the area involved.

Lastly there is *dysfunction* (*functio laesa*, or disordered function) due to the swelling and pain.

alarming symptoms. They are slower to develop and slower to leave. *Chronic infections*, like tuberculosis, may last over a period of years. They are caused by repeated invasions of organisms rather than by a continued single invasion. *Acute* infections may be become *subacute* or *chronic*.

Infections are further classified according to the type of exudate they engender such as serous, fibrinous, suppurative or purulent, serosanguineous, hemorrhagic, pseudomembranous, or combinations of the foregoing (see Chapter 5). Inflammations (as distinguished from infections) may be produced by any type of injury, physical, chemical, or bacterial. They may be classified as parenchymatous, alterative, or exudative (see Chapter 3); that is, the inflammatory reaction may be due to a degeneration of parenchymatous cells (degenerative) or the production of new cells (alterative, productive, or proliferative) or to the formation of an exudate (exudative).

An acute pyogenic infection gives rise to certain clinical symptoms and signs. First, redness (rubor) is seen if the area is near the skin. An inflamed area is red because of an increased number of open capillaries and a more rapid flow of blood (hyperemia). This may be seen easily in the frog's web. After stroking, a few scattered capillaries are seen; then, with more strokes, new capillaries come into view. Soon the entire field will be full of capillaries and, if stroking is continued, some of the blood vessels will break (rhexis). Severe streptococcic infections may destroy the blood vessels and cause hemorrhage by their lysing effect; staphylococcic infections, although equally or more severe, will not destroy tissue as much because of the reaction which they call forth.

Changes in capillary pressure and in permeability may be caused by variations in *temperature, by tisue activity, and by injuries. Heat produces filtration of fluid* through the capillary wall in one of three ways: (a) by producing capillary dilation, (b) by causing a rise in capillary pressure, (c) by actual injury to the endothelium, resulting in an increased permeability to colloids and a consequent lowering of the effective osmotic pressure. Local injury to the capillaries causes vasodilation, rise in capillary pressure, altered rate of blood flow, and an increase in endothelial permeability with resultant stasis.

Rigdon has studied *capillary permeability in areas of inflammation produced by* xylene. These capillaries show an increase in permeability for about thirty six hours after the local application of xylene. This is indicated by localization in the area of trypan blue, India ink, antitoxins, and vaccine virus. Chemically the skin may show all features of inflammation and yet there may be no localization of the dye. Different irritants affect the capillary permeability more (4 per cent sodium chloride) or less quickly (horse serum). Hyperemia and edema are not determining factors in permeability. *Most bacteria remain within the lumens* of the small blood vessels of the corium when injected intravenously or in the endothelial cells. Staphylococci may reach the extravascular tissues in *areas of inflammation by being phagocytosed by the* polymorphonuclear leucocytes within the blood vessel lumen and then carried through the blood vessel wall. The organism may also adhere or be phagocytosed *by the endothelial* cells severely injuring them, thus allowing the bacteria to penetrate.

Sectioning of the spinal cord has no direct effect on the development of focal inflammatory reaction unless shock is present—then it is retarded. Heparin has no effect on capillary permeability or inflammatory reactions of capillaries or leucocytes.

destruction of tissue whether that destruction follows trauma by mechanical, chemical, or *bacterial agents. Clinically, therefore, pyogenic infection* may end as follows:

1. *Resolution.*—Hyperemia occurs with little or no destruction of tissue. There is early and complete local immunity. The process ends in about twenty-four to forty-eight hours.

2. *Necrosis and Absorption.*—Infection goes a step further. There is some destruction of tissue; the dead tissue is quickly absorbed, and repair is rapid and complete.

3. *Suppuration or Formation of Frank Pus.*—There have been hyperemia and necrosis. The infection was severe enough for suppuration to occur; then immunity is established and repair follows.

4. *Sloughing and Gangrene.*—There is extensive necrosis of tissue due to its destruction by bacterial toxins and interference with the blood supply. *This is seen in streptococcic infections.*

Fibrosis or Scar Formation is the end result of healing in any infection where tissue cells have been destroyed. It is greater after wide destruction of tissue and is especially seen after fungus infections and syphilis.

Calcification is the end result of a tuberculous infection and implies its arrest, but it may follow traumatic injury or other infections (histoplasmosis, coccidioidal) and degenerative changes.

General Effects of Infection.—

Using our previous metaphor, the city at large may also be affected by the burning house (Chapter 3).

In addition to local defenses against bacterial invasion, the resources of the body as a whole are sometimes needed to overcome the invading organisms.

A systemic infection manifests itself through defense reactions. It causes *chills, fever, rapid pulse, leucocytosis, anorexia,* and *general symptoms of malaise.*

In systemic infection fever is helpful because the bodily functions and the forces of immunity work better with an elevated temperature. *It is clearly a defense mechanism.*

Warm-blooded animals (mammals) differ from those that are cold blooded (Pisces, Amphibia, Reptilia) in maintaining a stable temperature, which in man is 98.6° F. This may vary some normally. Often there is a postprandial rise to 99° F. Exceedingly high environmental temperatures prevent heat loss by convection and radiation, allowing regulation only by evaporation. This may cause hyperthermia, as in heatstroke, indicating an overpowering of the heat-regulating mechanism. We shall see in Chapter 11—Water balance, that the body temperature is regulated mainly by evaporation (*70 per cent of the heat is lost in this way during exercise, 25 per cent* normally). Other methods are convection and radiation. This requires sweating and increased circulation to carry blood from the interior to the exterior (where convection and radiation become effective). Therefore, a rapid heart rate and forceful beat are

The clinical symptoms and signs as well as the pathologic changes do not occur in sequence as indicated by this discussion. They occur more or less simultaneously.

The local effects of pyogenic bacterial invasion are accompanied by pus formation. Pus corpuscles are essentially polymorphonuclear leucocytes. They fight bacteria, release an enzyme inhibiting bacterial growth, stimulate the formation of thrombi in lymphatics and capillaries, and make possible the walling-in by a pyogenic membrane.

Bacteriophage.—It is thought by some that in addition to the cells described there is a local agent that aids in annihilating the infective organism. This substance is a protein formed from a precursor originating in the bacteria themselves, for it is formed from cultures grown in vitro as well as in vivo, where its origin is probably more complex. Bacteriophage is a Berkefeld filtrate of bacteria, which, when added to other bacterial cultures converts them usually from "smooth" to "rough," the latter being less virulent except the salmonella and a few other organisms. It seems to engulf them and therefore has been called bacteriophage. D'Herelle thought it was a living organism that destroyed the bacteria. Besredka called it an antivirus (virus against pathogenic bacteria). Other investigators think it a lysate (dissolving bacteria), a chemical substance (local antibody of the bacteria), a colloid suspension (killing by osmosis), an enzyme (digesting bacteria), or a phase in the life cycle of the organism (cyclostage). The exact nature of bacteriophage is unknown. Apparently it cannot be transferred successfully from one individual to another: its action is brief and bacteria will even thrive in its presence after a certain period of time.

A pyogenic infection is one in which the exudate may become purulent—therefore, the name pyogenic or suppurative. It does not always result in the formation of frank pus. Many texts speak of varieties of infections depending on the type of exudate that may occur; namely, serous, fibrinous, serofibrinous, catarrhal, purulent, fibrinous with necrosis of underlying tissue (pseudomembranous), and hemorrhagic. They also include inflammations in this category implying that such exudate may arise from any irritant such as turpentine or aleuronat. It is probably better not to classify infections in this manner because the type of tissue, the time element, the virulence, and amount of antigen and, above all, the resistance of the individual may produce many, if not, all types of exudates in the same tissue during the course of the same infection by the same organism. We have therefore chosen to include under the term pyogenic infection those bacteria which may cause suppuration, and we believe it is better to classify changes which may occur in tissues when the infection is arrested or rather when local immunity is great enough to make the environment unfavorable for bacterial growth and tissue invasion. It should also be said that the terminations of infections are usually given as resolution fibrosis or calcification. The latter are classified here as types of repair following

It is doubtful if injured or traumatized tissue will produce fever. This usually implies infection by a bacterial antigen. Certain protein sensitizations may produce leucocytosis, fever, and even dehiscence of the wound (as in the Arthus phenomenon). However, it is safe to say that postoperative fever is due to infection until proved otherwise. Furthermore, it is probably true that transient bacteriemia is a common sequel to operation in the nose and throat, rectum, kidney, bladder, and all organs normally contaminated. Such bacteriemias are quickly and easily overcome by the average patient.

In infections there is a reduction in heat loss due to vasoconstriction in the skin (causing the patient to appear cold and blue), a reduction in blood volume due to loss of water, and an increase in heat production due to the action of toxins on the heat center. This causes a sensation of chilliness and muscle contractions, which produce more heat. Soon there is an adjustment of heat production and heat loss, the capillaries dilate, and the skin becomes warm, but the whole balance is at a higher level. Barbour suggests the following sequence of events:

The bacterial toxin acts on the peripheral tissues (chiefly muscle) causing catabolic changes. *The catabolic breakdown products increase the affinity of the muscle for* water and cause the withdrawal of abnormal amounts of water from the blood stream. To compensate for the reduction of the volume of circulating fluid, blood is drained from the skin vessels. This makes the skin cold and calls forth a reflex "cold" response from the heat-regulating mechanism. This acts to increase vasoconstriction and hemoconcentration. Finally, the blood becomes warm enough for the nervous system to interpret the temperature as normal or neutral. The chill period has its counterpart in a healthy person by the body reaction to a cold plunge—there is vasoconstriction, diminished heat dissipation, shivering, increased heat production, slight rise in body temperature, blood vessels released from spasm, and stored heat eliminated and skin is warm. The fever period resembles the effects of immersion in hot water with rise in temperature, decreased heat dissipation, and increased heat production as a result of elevation of temperature of the tissue cells (Best and Taylor).

The metabolism in fever brings about changes in water and salt balance—at first anhydremia, later hydremia (this explains scanty urine in the early stages and ample exertion later). Chlorides are retained in the tissues during fever. After fever subsides they are lost in the kidneys and sweat. Tissue destruction is increased and therefore protein may be found in the urine. Carbohydrates spare protein and therefore should be given in fever, since proteins increase kidney work. Carbohydrate metabolism is unaffected and fat metabolism is not disrupted unless there is insufficient carbohydrate to burn the fat.

Fever is not a disease; it is a symptom and indicates that the body is fighting an invading organism. Fever may be absent in overwhelming infections where symptoms of shock prevail. The rectal temperature is about one degree higher than the temperature as ordinarily taken. Food and drink immediately preceding the taking of the temperature by mouth may alter the reading; therefore, the rectal temperature is perhaps more accurate. The pulse follows the rise in temperature, and its quality and rate are of great prognostic import.

There are many clinical types of fever. We speak of remittent, intermittent, and *relapsing types of fever; also of acute and chronic fevers.* The fastigium is the high point of a temperature curve.

1. *Remittent fever* is a fever in which the temperature goes higher in the evening and becomes lower in the morning but does not touch normal. This type is seen in severe general blood stream infections.

necessary. This gives rise to the bounding pulse. The pulse rate increases about ten beats per minute for each degree of fever. The entire mechanism is, according to Cannon, part of the function of the autonomic nervous system designed to produce "homeostasis" in man.

It is probably true that fever results from a decreased heat elimination rather than from an increase in heat production, although the latter does occur with an increase in the velocity of oxidative processes which in turn is due to heat retention.

Moderate increase in body temperature produces no ill effects and has many important functions. Although most textbooks speak of an increased antibody production and function, there is no proof for this statement. In fact (experimental evidence shows that in artificial fever specific antibody formation is inhibited and its destruction accelerated. Fever induced by foreign proteins is beneficial in chronic infections, and malaria has been very helpful in treating paresis. Hyperthermia produced by various electrical devices (short wave diathermy) will kill gonococci and spirochetes but may also cause the death of brain and other tissue cells.

Fever causes: a stimulation of circulation, increased capillary permeability, more phagocytic cells with greater activity to the inflamed area, more food and oxygen to the region of infection, and also more waste and CO_2 carried away from the site. These effects provide for a more rapid neutralization dilution and removal of toxic products which may be eliminated by increased activity of the lungs, kidneys, bowel, and skin.

The mobilization of cells is as important if not more so than the fever. In the treatment of paresis (see Chapter 9), hyperthermia by diathermy is not as effective as by malaria. Nor is the height of the fever as important as its continuation. Its good effects are probably due to the mobilization of macrophage and other types of reticulo-endothelial and lymphocytic cells.

Heat increases blood volume (contraction of spleen, water drawn from tissue spaces) and capillary filtration, and consequently an increase in the amount of lymph and plasma occurs at the atria or foci of infection. This filtration and the increase in blood circulation is made possible also by a reduction in the viscosity of the blood by fever. The work of the heart is thereby reduced. If hemoconcentration occurs and is not rectified, these effects do not ensue.

The explanation for diurnal variations in fever is not definitely known. We have noted that continued hyperthermia may be fatal to cells and to the body. Nature, therefore, gives brief respites more or less completely in intermittent and remittent types of fever. Some explanations for this are the antigen is forced into the circulation and then removed by the reticulo endothelial system; the antigen varies in amount and virulence from day to day; muscular activity during the day causes the rise in the evening which is followed by a fall the next morning due to a night's rest. In general, the intermittent fevers are less serious than the remittent, and a sustained high rise in temperature is usually an ominous sign.

The heat regulating mechanism is under the influence of the central and sympathetic nervous systems and if interfered with by anesthesia or injury, body temperature may be greatly altered. In the premature infant this same influence is manifest. Even in the infant at term external variations in temperature are not stabilized by the body mechanisms because the nervous system does not assume full control over muscles, blood vessels, sweat glands, and other glandular organs for some time. This is especially noted during surgery on young children where hyperthermia may occur easily.

For local and general therapeutic uses of heat, see Chapters 5, 6, 14, and 21.

Fever may be due to infections, to the postoperative absorption of toxic substances liberated by injured tissues (?), to neurogenic causes, as in brain injuries (near the third ventricle), to dehydration (anhydremia), to starvation, to lymphoblastic diseases such as Hodgkin's disease and lymphosarcoma, and to drug action (hypertonic glucose and salt, drastic cathartics, foreign protein, etc.).

It is doubtful if injured or traumatized tissue will produce fever. This usually implies infection by a bacterial antigen. Certain protein sensitizations may produce leucocytosis, fever, and even dehiscence of the wound (as in the Arthus phenomenon). However, it is safe to say that postoperative fever is due to infection until proved other wise. Furthermore, it is probably true that transient bacteriemia is a common sequel to operation in the nose and throat, rectum, kidney, bladder, and all organs normally contaminated. Such bacteriemias are quickly and easily overcome by the average patient.

In infections there is a reduction in heat loss due to vasoconstriction in the skin (causing the patient to appear cold and blue), a reduction in blood volume due to loss of water, and an increase in heat production due to the action of toxins on the heat center. This causes a sensation of chilliness and muscle contractions, which produce more heat. Soon there is an adjustment of heat production and heat loss, the capillaries dilate, and the skin becomes warm, but the whole balance is at a higher level. Barbour suggests the following sequence of events:

The bacterial toxin acts on the peripheral tissues (chiefly muscle) causing catabolic changes. *The catabolic breakdown products increase the affinity of the muscle for water* and cause the withdrawal of abnormal amounts of water from the blood stream To compensate for the reduction of the volume of circulating fluid, blood is drained from the skin vessels. This makes the skin cold and calls forth a reflex "cold" response from the heat-regulating mechanism. This acts to increase vasoconstriction and hemoconcentration. Finally, the blood becomes warm enough for the nervous system to interpret the temperature as normal or neutral. The chill period has its counterpart in a healthy person by the body reaction to a cold plunge—there is vasoconstric*tion, diminished heat dissipation, shivering, increased heat production, slight rise in* body temperature, blood vessels released from spasm, and stored heat eliminated and skin is warm. The fever period resembles the effects of immersion in hot water with rise in temperature, decreased heat dissipation, and increased heat production as a result of elevation of temperature of the tissue cells (Best and Taylor).

The metabolism in fever brings about changes in water and salt balance—at first anhydremia, later hydremia (this explains scanty urine in the early stages and ample exertion later). Chlorides are retained in the tissues during fever. After fever subsides they are lost in the kidneys and sweat. Tissue destruction is increased and therefore protein may be found in the urine. Carbohydrates spare protein and therefore should be given in fever, since proteins increase kidney work. Carbohydrate metabolism is unaffected and fat metabolism is not disrupted unless there is insufficient carbohydrate to burn the fat.

Fever is not a disease; it is a symptom and indicates that the body is fighting an invading organism. Fever may be absent in overwhelming infections where symptoms of shock prevail. The rectal temperature is about one degree higher than the temperature as ordinarily taken. Food and drink immediately preceding the taking of the temperature by mouth may alter the reading; therefore, the rectal temperature is perhaps more accurate. The pulse follows the rise in temperature, and its quality and rate are of great prognostic import.

There are many clinical types of fever We speak of remittent, intermittent, and relapsing *types of fever;* also of acute and chronic fevers. The fastigium is the high point of a temperature curve.

1. *Remittent fever* is a fever in which the temperature goes higher in the evening and becomes lower in the morning but does not touch normal. This type is seen in severe general blood stream infections.

A. B. C. D.

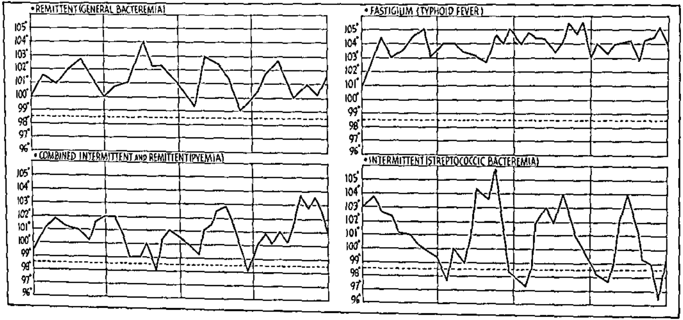

FIG. 24.—Diurnal charts showing types of fever: *A.* Remittent type. The temperature is elevated in the evening and falls in the morning but does not reach normal. (General bacteriemia *due to pneumococcic* empyema thoracis.) *B.* Combined intermittent and remittent type. The curve touches normal or goes below (intermittent type). (Multiple furunculosis with septic embolus in the *kidney on the fourth day.*) *C.* Type showing a fastigium or high plateau during the height of the disease. (Typhoid fever.) *D.* Intermittent type. (Streptococcic bacteriemia due to diffuse cellulitis of the arm.)

2. *Intermittent* fever also shows diurnal variations, but unlike remittent fever, it goes to normal or subnormal and then goes up again (also called "picket fence" type). This type is seen in malaria and in acute infections.

3. The *relapsing* type is seen in the estivo-autumnal type of malaria and in relapsing fever. *The temperature may be remittent or intermittent and then return to* normal for a variable period, only to ascend again.

Various combinations are seen in pyemias, and special types occur in typhoid and pneumonia.

Bacteriemia implies that pathogenic bacteria have successfully invaded the blood stream and its macrophage system. A positive blood culture may show the type of organism. A negative blood culture, however, does not necessarily rule out a bacteriemia. The macrophage system may be full of bacteria which do not live long in the blood plasma. Conversely, the mere presence of bacteria in a blood culture, in the absence of clinical symptoms, does not indicate a bacteriemia in the pathologic sense. Bacteria probably do not multiply in the blood stream unless the reticulo-endothelial system is rendered inactive (experimentally) or is overwhelmed by bacteria. Bacteriemias are therefore transient or intermittent unless the focus, such as a spreading cellulitis, constantly feeds in virulent organisms or there is an intravascular focus (purulent phlebitis, septic thrombophlebitis, pulmonary thrombophlebitis, acute or subacute bacterial endocarditis, or an overwhelming bacteriemia from any cause). Such bacteriemias are sustained. With the use of penicillin it is possible in bacteriemias to obtain sterile cultures from the blood stream and the acute focus. However, unless the focus is drained the septic fever and leucocytosis, which have receded, may soon return. In such cases the bacteria are quickly removed from the blood stream by the reticulo-endothelial system and inhibited by the drugs.

Septicemia is an old term; as usually employed, it includes bacteremia and toxemia (presence of toxins in the blood). The latter is seen in tetanus and diphtheria.

The word toxemia is used very loosely to include states with hypothetical toxins such as the toxemia of burns, intestinal obstruction, eclampsia, and goiter. The toxins of these diseases have not thus far been demonstrated in the blood stream and may be due to a combination of causes; namely, infection, dehydration, hemoconcentration and its effects, anoxemia, and azotemia.

Pyemia means bacterial infection with multiple abscess formation.

Every fever is preceded by a chill.

Hypothermia does not seem to be a compensatory mechanism in infections unless accompanied by shock. (See Chapter 14.) Indeed shock may be associated with a high fever when due to infection. Heat production is due to activity of skeletal muscles chiefly, and, to a lesser extent to glandular action, especially in the liver and kidney. Cold normally stimulates metabolism to increased heat production. This is due to increased production of adrenalin and thyroxin, causing increased tissue oxidation, and to muscular activity. Cutaneous arterioles contract to diminish heat loss and blood is diverted to vital organs (brain, heart, abdominal viscera). Blood pressure may rise. Water is lost from

the blood and diverted to muscles and parenchymatous organs (liver) causing a reduction in blood volume; hemoconcentration may result. Long exposure to cold, according to Wright, may cause a fatigued individual to go into a deep sleep. While in this unconscious state body temperature falls, coma sets in, and death results. A fall in temperature depresses the dissociation of oxyhemoglobin and tends to lower oxidation in the tissue.

Prolonged hypothermia has been artificially induced in patients afflicted with incurable cancer. Here it is said to reduce metabolic activity of cells, slowing up the process of cell division—obviously a temporary accomplishment and not curative.

Experiments on animals with severe infections show that hypothermia does not depress leucocytosis or phagocytosis. Its effect on circulating antibodies has not been ascertained. However, nonlethal pneumococcic infections are changed to lethal pneumococcic infections by lowering body temperature of rabbits to 88° to 90° F. Local chilling of the skin at the site of inoculation inhibited the local inflammatory reaction of the skin.

Crymotherapy or Cryotherapy.—Cold therapy is used in heatstroke and excessively high fever. It may be used locally in certain types of gangrene where amputation is necessary and in sprains to delimit exudation. If cold is used to a degree resulting in refrigeration, it is known as crymotherapy (from *krimo*, icy cold). Cryotherapy (from *krios*, cold) is a milder form of cold. Cold is not indicated locally in the treatment of infections for it lowers oxidation in the tissues when this is undesirable, especially during the period of stasis, q.v. Cold delimits local inflammatory response and decreases oxygen requirements of tissue cells and causes a lowering of their metabolism. It has the same effect on the invading organisms, thereby holding the infection in status quo. Meanwhile the migration of blood and leucocytes has been delayed. *Due to relief from pain, cold is better tolerated than heat and its prolonged use may* cause irreparable damage to cells and capillaries. When the cold is removed, the infection may spread wildly uninhibited. Furthermore, due to local anoxemia anaerobes may grow.

The patient may not realize he is having a chill; he may merely request another blanket. *The exact cause of chill is unknown.* It was formerly thought to be due to blood leaving the periphery of the body. But chills occur when the patient is surrounded by hot water bottles and blankets and when the skin is red and rectal temperature high. In children a chill may be a convulsion. A rigor is a severe and protracted chill. Some believe it to be due to a toxic action on the motor area of the brain. The chill is obviously a mechanism for raising body temperature rapidly; the feeling of warmth, like the sweat after a chill, is part *of the bodily mechanism for rapidly lowering body temperature.* This is reversed in shock, for here the patient feels very warm so that he wants to remain quiet and he sweats—both are physiologic methods for rapidly lowering body temperature. *It is perhaps unwise to interfere with either* mechanism by using cold in the former and heat in the latter. It is also unwise to augment the reactions by using external heat in a chill with a high body temperature or cold in shock with a low body temperature. *If* the patient is able to express his feelings, his comfort should be considered; if not, he should be warmed or not according to his environmental temperature.

The body signal that an infection is present is fever.

Continued fever is usually due to an infection. Such infections may be due to pyogenic bacteria as in subphrenic abscess or other abscesses or to malaria, typhoid, tuberculosis, or syphilis. ***Sometimes the cause is very obscure.***

A patient who has an infection has fever unless (1) it is an overwhelming infection, like a streptococcus septicemia due to septic abortion (where the load of bacteria in the body is too great and the patient is

Fig. 25.—Granuloma at the root of a tooth. The saclike projection is composed of granulation tissue. It is sclerosed at its periphery, forming a connective tissue capsule which *surrounds the cystlike cavity. Such areas are said to be the silent and symptomless* foci of infection. They are probably "tomb stones" marking previous sites of injury or infections which have been successfully overcome.

overcome without any evidence of resistance); (2) the infection is so mild that it is completely localized by the local immunizing forces; (3) the infection occurs in tissue from which absorption does not occur readily (for example, brain) or is present on the surface of the body where the antigen does not accumulate under pressure if drainage is ade-

quate. Fever may occur as a result of protein injection (for example, serum sickness, etc.) and other causes previously discussed. However, when a patient has fever, it should be considered as the result of an infection due to bacteria *until proved otherwise.*

"The fever itself is nature's remedy."

—Sydenham

Changes in the Blood Picture.—The infected patient has also an increase in the number of white blood cells (leucocytosis).

The bone marrow as a hematopoietic organ must be *considered as a unit.* Weltzel showed that in the human adult it has a volume of 1419 c.c., which is thirteen times that of the spleen and almost equal to that of the liver. Since the total amount of tissue *is constant, the proportion of erythropoietic to granulopoietic tissue is consant.* This is about 75 per cent for white and 25 per cent for red cells. Beck states that from three to twenty times more tissue is devoted to the production of granulocytes than to the production of erythrocytes. The volume of granulopoietic tissue is nine and one-half to twelve times that of the spleen. The red blood cell makes about 50 billion round trips and then dies. Bone marrow replaces a trillian erythrocytes each twenty-four hours. These are destroyed and taken up by the reticulo-endothelial system, especially the spleen liberating 25 Gm. of hemoglobin. There are about 100 mg. of iron in 25 Gm. of hemoglobin. Most of the liberated hemoglobin is used over to make new red blood cells. Eighty-five milligrams of iron from old red blood cells is so used each day and 15 mg. is obtained from ingested food—a 100 mg. of iron is a daily requirement.

Blood platelets are present in the ratio of 1 to 20 red blood cells in the circulating blood. They come from the megakaryocytes. They are *increased* after a meal of meat, after hemorrhage, in anaphylaxis, in myeloid leucemia, and after surgery. They are decreased in purpura, aplastic and pernicious anemia, and leucemia.

An increase in white cells is evidence that the "fighting soldiers" are mobilized and ready to repel the invading organisms. Certain conditions are necessary for a leucocytosis to occur:

1. The organism must be of the type calling forth leucocytes.
2. The infection must not be overwhelming.
3. The blood-forming organs (bone marrow) must be normal and able to produce leucocytes.
4. The infected area must be under pressure so that absorption can take place.

Variations in the response will occur depending on the acuteness of the infection and on the kind of tissue that is infected. The vascularity and density of the tissue will affect the absorption and consequently the response. In bone, the response is sudden and pronounced. In the brain no lymphatics are present and absorption is slow due to softness of tissue. Therefore, a brain abscess may occur without fever or leucocytosis.

Walker's index *may be a guide to prognosis.* Ten thousand white blood cells per cubic millimeter may be considered as an average normal blood count; of this number, about 70 per cent are polymorphonuclears.

For every increase of 1 per cent in the polymorphonuclears, there should be an increase of 1,000 in the white cell count. Expressed as a ratio, the normal index (with 10,000 white cells and 70 per cent polymorphonuclears) is 0/0. If the total count is 11,000 and the per cent of polymorphonuclears is 71 per cent, the index is 1/1. In severe streptococcic infections there is a high per cent of polymorphonuclears. If the index is 1 or higher, the prognosis is good; if it is below 1, it is not so good. Say the total count is 30,000 and the polymorphonuclears 84 per cent. This gives an index of 20.14 and a good prognosis. The resistance is high and the virulence low. Repeated counts are necessary in the application of Walker's index. If the sulfonamides have been used, it may not be used accurately. This is not true of penicillin which apparently does not affect hematopoiesis. The Schilling counts are routine laboratory procedures. These also may be distorted by the sulfonamides.

Ponder, Garrey, and others found in normal persons at rest white cell counts of 4,700 to 11,500 and in normal persons during active exercise, counts of 3,500 to 11,500; that is, about the same. Slight normal variations occur also after meals, from nervous or psychic factors, pain, rapid breathing, etc. Perhaps this physiological leucocytosis is due to a vascular readjustment. In general, leucocytes fight infection, are phagocytic, and produce a protease which weakens the antigen. Lymphocytes come later in the course of an infection and aid in the production of antibodies, perhaps macrophages and fibroblasts.

The change in the total number of leucocytes indicates the resistance of the patient; the per cent of polymorphonuclears indicates the virulence of the organism. If the patient has a great resistance the white count should go up.

We have previously seen that at any one time the bone marrow consists of 75 per cent leucocytes and 25 per cent red blood cells, although the total red cell count is much greater. The life of the polymorphonuclear leucocyte is only a few days, for it is constantly being destroyed in its fight against invading organisms. Five to ten billion new cells must be made by the bone marrow each day to make up for this destruction. Red blood cells live thirty to forty days and are destroyed by wear and tear. Lymphocytes are formed in the lymph glands and lymphoid tissue. Lymphocytes live twenty-four hours. Most of them eventually pass into the lumen of the bowel presumably to neutralize the toxins of the intestinal contents by the action of lipase which they contain. They may be related to digestion and stored in the lymphoid follicles and then released. Eosinophiles and lymphocytes disappear from the peripheral circulation of a dog's blood when complete lymphatic obstruction is produced.

Eosinophilia is usually caused by intestinal parasites, trichinosis, arsenic poisoning, eosinophilic leucemia, dermatitis herpetiformes, periarteritis nodosa, Hodgkin's disease, and lymphosarcoma. A variable cause is allergy.

Usually in infections we find a leucocytosis. Other conditions in which high leucocyte counts occur are protein shock, allergy, and intestinal obstruction, especially in mesenteric thrombosis; they also occur after hemorrhage (relative and absolute leucocytosis). Usually, however, a high leucocyte count means infection.

The term *leucopenia* is used to denote a low white cell count.

According to Wright, leucopenia is due to toxic inhibition of bone marrow activity or an increase in the antileucocytic ferment. In the absence of any of the commonly known causes for leucopenia, infection associated with it denotes a poor resistance. It is in such individuals that bacteria may cause extensive sloughing, as in gangrenous stomatitis or spreading gangrene of the abdominal wall. Here the bacteria grow in symbiosis without restriction. It is the "soil" that permits such growth rather than the "seed." An infected, diseased, traumatized, or immature erythrocyte or leucocyte may be quickly removed from the circulation by the reticulo-endothelial or macrophage system. This may account for the swollen lymph nodes and enlarged liver and spleen in many infections, especially those with a leucopenia where, in addition to the removal of inadequate cells, the virus or other antigen must be eliminated.

Lawrence lists the causes of leucopenia as follows:

1. Diminished manufacture of leucocytes by (a) simple inhibition, (b) maturation arrest, (c) aplasia of bone marrow, (d) infiltration of bone marrow with foreign cells.

2. Increased elimination of white blood cells, as in an empyema cavity or through normal channels such as the gastrointestinal tract, lungs, spleen, or liver.

3. Increased rate of destruction in the peripheral blood due to either abnormal white blood cells or to abnormal substances in the blood stream causing their destruction.

4. Redistribution of the white blood cells in the vascular channels such as occurs with foreign proteins.

5. Redistribution of the white blood cells in the body as a whole (leucopenic phase of leucemia).

Granular leucopenia or granulopenia (Haden) is caused usually by (1) a deficient quantity of bone marrow tissue as seen in aplastic anemia, (2) impaired marrow function (aminopyine intoxication produces a qualitative and Banti's disease a quantitative decrease in function, (3) mechanical barrier to the emergence of cells from the bone marrow as in leucopenic myeloid leucemia.

We have frequently encountered leucopenia in a spreading peritonitis. Usually this has been the result of a large amount of semipurulent exudate in the peritoneal cavity. An abscess may precede an agranulocytosis but theoretically it cannot occur when this condition is present because the polymorphonuclear cells are absent. However, a collection of lymphocytes may occur as in empyema of the gall bladder. In typhoid fever with leucopenia osteomyelitis may occur in which frank pus is present.

The sulfonamides may produce impaired marrow function. Therefore, some have advised that these drugs should not be used in the presence of a leucopenia. This cannot be accepted as a general rule. If the leucopenia is due to the bacteria, the drugs may be of inestimable value and the leucopenia may be converted into a leucocytosis. If, however, the drugs cause the leucopenia, they should not be used because it is the leucocytes that annihilate bacteria and not the sulfonamide drugs.

There are certain kinds of infection associated with leucopenia. These may be remembered by the following mnemonic: M_3, T_2, I_2, A. In *measles, mumps,* and *malaria* there is a high fever, but the leucocyte count is low. This is also found in *typhoid, tuberculosis, influenza,* and, at times, in *infectious mononucleosis,* although here there is a lymphocytosis. *Agranulocytosis* is the complete or nearly complete absence of the granular leucocytes from the bone marrow and the blood. It is due to certain drugs and toxic agents as well as to infections.

Red blood counts are important to detect hemoconcentration or hemodilution. Sedimentation rates are increased in widespread infections as in

Red blood counts are important to detect hemoconcentration or hemodilution. Sedimentation rates are increased in widespread infections as in

as liver and muscle, normally contain anaerobic organisms. They are nonpathogenic unless contaminated by streptococci or other organisms. This explains subcutaneous emphysema (collection of gas) in simple fracture or in contusions where there is no break in the skin and makes us realize that not all infections with gas production are due to the fatal varieties of anaerobes. Some are probably due to gas bacilli and streptococci growing in symbiosis. These are dangerous. Zinc peroxide and the sulfonamides may be used locally. Experiments are conflicting in their results. *This may be due to different types of indigenous organisms in* the animals used. For example, if many streptococci were present in the tissues of the animal they would consume oxygen, producing a favorable environment for the anaerobes. In such cases oxygen through zinc peroxide and bacteriostasis of the streptococcus would inhibit the anaerobes.

4. *Streptococcus pyogenes* produces diffuse cellulitis, phlegmon, lymphangitis, lymphadenitis, and such distinct entities as Ludwig's *angina, septic abortion, septic band, septic throat*, etc.

In spite of work done by Menkin (see Chapter 5), there is ample evidence that hemolytic streptococci from human hosts rapidly liquefy or dissolve human fibrin. This is not true of streptococci isolated from the cow, horse, rabbit, or guinea pig. Other bacteria tested and found to be fibrinolytically negative were *Streptococcus viridans*, the pneumococcus, *Bacillus typhosus, Bacillus coli, Bacillus dysenteriae*, and the influenza bacillus. Certain strains of staphylococci cause a slight softening of the human plasma clot if the reaction is allowed to continue for eighteen to twenty four hours. Undoubtedly both the fibrinolytic action of the streptococci and the modest tissue reaction they engender play a role in the tendency for the diffuse infections from streptococci to spread.

Infection may invade the entire body through the blood vessels and lymphatics, causing death. It is well to remember the aphorism: "Never enclose a streptococcus in a wound—leave it open," for it is frequently found with anaerobes and can itself exist anaerobically. A wound is better left open if infection is apt to occur. Localization with pus formation may and frequently does occur.

5. *Bacillus coli communis (Escherichia coli)* is an inhabitant of the gastrointestinal tract and may be present in suppurative appendicitis, diverticulitis, etc. It causes dark necrotic sloughs of fascia, has a foul odor, and produces gas in the tissues. It tends to localize ultimately.

6. *The pneumococcus (Diplococcus pneumoniae)* produces pneumonia, pneumococcic peritonitis, and empyema, with pus formation. The exudate is rich in fibrin and therefore the pus is found in large clumps which hang together.

7. *Bacillus typhosus (Eberthella typhosa)* produces typhoid fever. Occasionally it produces suppuration in bone and in parenchymatous organs.

8. *Bacillus pyocyaneus (Pseudomonas aeruginosa)* is a harmless bacterium but it frightens the patient because it forms green pus and has a musty odor. It is a secondary invader.

9. *The gonococcus (Neisseria gonorrhoeae)* produces gonorrhea, salpingo-oophoritis, pelvic peritonitis, suppurative arthritis at times, and even endocarditis.

10. *Anaerobic or gas bacilli* are a group of organisms and include the bacillus of malignant edema *(Clostridium sporogenes)* (the vibron septique) and *Bacillus welchii (Bacillus aerogenes capsulatus*, or *Clostridium perfringens)*. Other members of this group are *Clostridium sordellii; Clostridium septicum norgii; Clostridium sporogenes*, and *Clostridium histolyticum*. They cause gangrene by their toxic action and produce gas in the tissues. Death is due to early septicemia. The *Clostridii welchii* are said to produce three kinds of toxins: hemolysin, dermonecrotic, and lethal. These may be separate or part of the combined effects of toxins and distention of the tissues with gas. Some tissues, such

Chapter 5

CLINICAL TYPES OF TISSUE RESPONSE TO BACTERIAL INJURY AND CLINICAL TYPES OF SUPPURATIVE INFLAMMATION

Suppurative inflammation is seen clinically in two chief forms, localized and diffuse. *The localized type is usually caused by the staphylococcus,* which incites a vigorous reaction in the tissues. It is this reaction with its blood, cells, fibrin, and plasma which causes the localized variety to remain within the confines of its pyogenic membrane, as we have noted in Chapter 4. The diffuse variety is usually *caused by the streptococcus* which sneaks stealthily into the tissues, and although less virulent than the staphylococcus, it is more apt to spread because the local reaction is weak. This spread gives rise to many complications and sequelae which are not so common in localized types. The exudate offers tangible evidence of the difference in resistance. The former with its destructive onset causes the formation of pus; the latter calls forth a serosanguineous fluid, the result of damaged, dilated, leaky capillaries with very little necrosis at first so that normal tissue architecture is preserved, later to be destroyed.

We must not get the idea that the two types are always and unalterably separate and distinct. It is well known that the staphylococcus may spread wildly due to unusual virulence or lack of local resistance, giving rise to a serious variety of diffuse cellulitis and general bacteriemia. The reverse may be true of the streptococcus which may early form an abscess. Then, too, both varieties may be mixed together, causing a devastating destruction of tissue by their symbiotic activity.

In this chapter we shall first discuss localized infections as exemplified in a form of skin abscess, the boil or furuncle. An abscess is a cavity containing pus. It may occur anywhere in the body. Its clinical manifestations *will depend on the causative organism, the type tissue involved,* and its location. Thus an abscess in loose tissue gives rise to fewer and less severe symptoms than one in dense tissue. Brain abscess, carbuncles, boils, and perinephric abscess may all cause pain, but there may be little or no fever or leucocytosis until the area involved is large and under pressure. Contrast this with osteomyelitis and liver or kidney abscess where there is early and severe pain, high fever, and a great leucocyte response. The pain coupled with the general reaction leads to the diagnosis and the location of the abscess.

We must also consider diffuse types of infection, since both varieties are commonly seen in the hand; a discussion of infections of the hand is pertinent.

THE LOCAL ABSCESS, OR BOIL

By carefully studying the manifestations of a boil, which may be easily observed, we may learn to understand any local infection or abscess anywhere in the body. The normal skin is full of little pits. Some of these permit sweat to pour out (sweat gland ducts); others enclose the roots of hairs (hair follicles), which in turn are lubricated by sebaceous glands (see Chapter 16). Bacteria get into the hair follicle and are usually harmless. Should the follicle or duct become occluded with oil or dirt (comedone or blackhead), the bacteria will grow. Bacterial infection in the follicle destroys cells, calls forth an inflammation, and, as we have seen, the first thing that happens is an increase in the blood supply known as active hyperemia. As a result of this, the hair follicle swells and its opening closes completely. Bacterial growth is increased in this closed, warm, moist space. Microorganisms proliferate rapidly under these conditions. In the last chapter we studied the surgical pathology of inflammation. Let us now compare this with its clinical manifestations, as shown in Table II.

These stages do not necessarily occur separately and in consecutive order. Most of them, as we have already learned, progress more or less at the same time; however, this outline gives us a graphic picture of the progress of localized infections. In addition to these local manifestations, there may be general symptoms and signs. These are chills, fever, leucocytosis, malaise, and anorexia. They vary with the degree of systemic involvement. (See Chapter 4.)

TABLE II

STAGES OF INFECTION

SURGICAL PATHOLOGY	CLINICAL SIGNS AND SYMPTOMS
Hyperemia	Heat (*calor*), redness (*rubor*)
Exudation	Swelling (*tumor*)
Stasis (thrombosis of capillaries and lymphatics)	Beginning of localization
Necrosis (due to bacterial toxins, pressure, and erepsinlike enzymes)	Pain (*dolor*), tenderness
	Pus, sensation of softening; late, fluctuation
Suppuration	Hard area, or wall, around the inflamed zone
Immunity (pyogenic membrane)	"Proud flesh," if excessive
Granulation	New skin
Epithelialization	Scar

The infection starts, then, in a walled-off, closed cavity. Active hyperemia occurs, warning nature of local trouble by chemical and nervous stimuli. Exudation follows. Then the active flow of blood is slowed down (stasis). This permits local plugging of the capillaries and lymphatics by thrombi.

Menkin has shown that phagocytosis is absent at first. The preliminary reaction is one of exudation only. After a few hours granulocytes appear in the wound. These are later replaced by macrophages. This, in part, explains the fallacy of early incision in infections, before "localization" has occurred.

We shall see in Chapter 14 that loss of blood plasma causes the capillaries to become filled with cells. This packing of cells in the capillaries has a twofold action. It prevents reabsorption of the lost plasma so that it may act as an irrigating and diluting fluid and permits local thrombi to form. Certainly this is the cause of stasis in infection. The bacterial toxins render the capillaries more permeable, allowing plasma to exude and thereby limiting reabsorption through the capillaries. Menkin believes that, contrary to popular opinion, the reason for staphylococcic infections remaining localized and streptococcic infections spreading is the extreme reaction created by the staphylococcus. Menkin found that aleuronat and other irritants are fixed in the tissues as a result of mechanical blockade of the lymphatics by intraluminal plugs of leucocytes and coagulated plasma. Trypan blue, when injected into inflamed areas, is retained; in normal areas it is absorbed. With staphylococci, this blockade is established in one hour; with streptococci, it takes forty-five hours (pneumococci, about six hours). The difference in rapidity with which mechanical obstruction is set up may explain the difference in invasive qualities of different bacteria. Staphylococci produce a mild systemic reaction because of their local toxicity; streptococci produce severe general reactions because of their mild local reaction. Menkin's work also explains the good results obtained from prophylactic induction of inflammation in the peritoneal cavity and joints.

We learned in the previous chapter that when either crystalloids or colloids are injected into an experimental abscess after approximately six days, they are not absorbed. These experiments show what happens in a boil or furuncle. Nature closes the tiny capillaries so that the infection will be kept in situ. Sometimes the infection is so virulent or under such terrific pressure that the tiny blood clots are forced out or destroyed. In this event, multiple septic emboli will be carried to distant parts of the body, causing multiple boils or abscesses, *pyemia*, or *septicopyemia*. In the center of the inflamed area the bacteria are destroying tissue (necrosis); should this process of destruction continue, blood clots in capillaries (thrombi) may also be destroyed, with resulting *bacteriemia*.

Nature puts her soldiers (leucocytes and tissue wandering cells) to work. They surround the infected zone until finally local immunity is established. As a result of this battle many dead and living polymorphonuclears are left in the necrotic cavity. These, with cellular debris, lymph, and serum, cause suppuration or the formation of pus. We have spoken of a necrotic cavity. A cavity must have a wall. In a boil this wall is not normal tissue. It is granulation tissue and contains tissue wandering cells, polymorphonuclear leucocytes, lymphocytes, fibroblasts, and endothelial cells. These cells, aided no doubt by humoral antibodies, bring about a local immunity. Furthermore, the closure of the capillaries in the "wall" fortifies the body against the spread of the infection. In other words, there is a living immune barrier to the progress of the infection. On its periphery, capillaries and lymphatics are open, so that fresh blood may be carried to it and debris carried away. This wall of granulation tissue is known as the "pyogenic membrane" or "leucocytic barrier."

Inside the cavity is a "core." The core is made up of necrotic tissue, bacteria, polymorphonuclear cells, fibrin, connective tissue, and cellular debris. The core is in the center because it is surrounded by pus. A solid structure in a liquid medium, with equal pressure on all sides, will work

toward the center by centripetal force. As pus accumulates, it exerts an outward force also (centrifugal); this makes the skin over a boil tense and thin. Because of this pressure and the digestive action of the leucocytic ferments, the skin breaks: the boil has "opened itself." Pus exudes, followed in a few days by the core. The cavity which is left is lined, but not as yet filled, with granulation tissue. Filling gradually takes place and the wound heals by second intention (see Chapter 3). The only difference between this granulation tissue and the kind we find in wounds healing by first intention is that this tissue is filled with immunizing bodies and many more polymorphonuclear cells.

Certain deductions may be made from this study. Trauma, as by squeezing a boil, would break down the "pyogenic membrane." This would not destroy the wall but it would injure it so that the bacteria that were still present would not be held in check. Infection would spread and a second boil would probably develop. One cannot prevent infections from occurring. However, one can bring about early resolutions. The occluded hair follicle should be opened. This is best accomplished by scrubbing the small reddened area with ether, carbon tetrachloride, or grease soap and then washing with alcohol (70 per cent by weight). This will frequently "abort" a boil. Heat aids in localization, especially after the second or third day, because it increases the blood supply to the part. This is done by causing capillary dilatation.

This is not only true on the surface of the body but internally as well. According to Krogh, heat produces a dilatation through sympathetic axon reflex paths as well as through true spinal reflexes. Ruhmann inserted a laparoscope through a small incision and directly observed that the application of heat (46° C.) to the skin of the abdomen brought about a reflex hyperemia of the corresponding part of the intestines in four to six seconds. Bisgard has shown experimentally that heat on the outside of the abdomen slows peristalsis, whereas cold increases it. The reverse is true when hot or cold drinks are ingested. This accounts for the benefits of heat on the abdomen in intra-abdominal inflammations, even though it produces no rise in internal temperature. We have noted that the dilated capillaries in an inflamed area become more permeable, allowing exudation of plasma, and that the exuded plasma cannot be reabsorbed except through the lymphatics. Increasing this dilation allows more plasma and more cells to reach the inflamed area, thus aiding greatly the establishment of local immunity. Cold has the reverse effect, causing constriction of the vessels, slowing of capillary blood flow, increasing capillary permeability through oxygen lack or injury to capillary wall, loss of water into the area, and resulting local anhydremia, thereby increasing stasis and hastening the destruction of tissue.

Brooks and Duncan experimented with temperatures of 10, 40, and 37° C. to determine the effects of heat and cold on wounds. Low temperatures delay the inflammatory response, whereas wounds treated with heat show an accelerated reaction. Both return to the average progress when discontinued. My colleagues and I have experimented with clean and contaminated wounds in guinea pigs and incidentally we observed the effects of heat and cold on wounds. We concluded that cold was not indicated in the treatment of infections even during the first twenty four to forty-eight hours. Cold slows bacterial growth but also the metabolism of cells and their vital blood supply. The most that can be hoped for is a delay in the ultimate reaction. If a part is to be sacrificed as in gangrene of the extremities we are not concerned over the effect of cold on tissue cells nor the possibility of devitalization of such cells. However, in

most instances we are deeply interested in maintaining a viable well-nourished cell even though by so doing we create a more favorable temperature for bacterial growth, for the ultimate destruction of bacteria is by the cell. Since exudation is most prominent during the first twenty-four to forty-eight hours, the important process would be limited by cold. Furthermore, if the sulfonamides or penicillin is given, these drugs cannot reach the area of infection so easily.

Cold used intermittently is followed by vasodilatation. This is an irritating and traumatizing maneuver and should not be used. In all intra-abdominal inflammations cold masks symptoms and produces a delusive improvement.

Pus manifests itself clinically by a central area of softening and late in large superficial abscesses by *fluctuation*. By tapping lightly over the softened center we may elicit a small wave, showing the presence of thick fluid in a closed cavity (also found in incompletely filled cysts and cold abscesses). This, together with the soft center and craterlike edge, assures us of complete localization. Should the surgeon elect to open the furuncle, he will do so through the center. He will then observe the incision to see that it remains open long enough for granulation tissue to fill the cavity. He does not cut through the wall because he knows that this will carry infection into healthy tissue. He does not dare cut away nature's wall of defense. Later he will lift out the loosened core, because it is a foreign body and would delay healing if not removed or extruded by nature.

The treatment of an abscess may be dogmatically stated as follows:

1. Wait for localization. This implies the establishment of local immunity and complete formation of the pyogenic membrane.

2. Provide adequate drainage. This permits "flushing" by pus and avoids pus under pressure.

3. Remove foreign bodies. These prevent free egress of pus and delay repair. In the boil, the "foreign body" is the core. This will usually extrude itself. It should never be torn from its attachment to the granulation tissue.

4. Assure obliteration of the dead space. This is obtained by keeping the wound open so that healing will occur "from the bottom up." Tubes or drains are used for all large abscesses and deep collections of pus. They are foreign bodies deliberately introduced to maintain drainage. They should be avoided whenever feasible, especially in joints and tendon sheaths because, like all foreign bodies, they delay healing, inciting more scar formation.

5. Keep the part at rest. This delimits absorption, prevents injury to surrounding tissue and to the pyogenic membrane, and facilitates repair. Avoid frequent dressings, irrigations, and packings.

6. Give attention to the patient as a whole. Maintain the water balance; give blood transfusion, drugs, etc., if needed.

MULTIPLE BOILS

Sometimes multiple boils will form in a particular area, such as the axilla, the back of the neck, or the scalp. These are due to a decreased

local tissue resistance, such as may be brought about by mechanical friction (collar rubbing the neck), premature incision, or chemical irritation (depilatory, antiperspirant, or deodorant under the arm or strong "tonics" in the scalp). These boils are best treated conservatively; that is, protection with padded bandage and the use of heat. This treatment permits local immunity (local autovaccination) to occur and prevents new "crops" from forming. General furunculosis, such as afflicted the pious and devout Job, is due to *pyemia*. What is known as *Welch's Law of Reciprocal Immunity* is present. If twenty or thirty boils should suddenly occur, the individual would quickly perish. When, however, the boils occur in crops, as they usually do, the patient builds up an immunity to the staphylococcus and the latter, in turn (perhaps because of the slow evolution of the immunity), builds up a resistance to the patient's antibodies—a reciprocal immunity is present. If attention is given to diet, rest, and the general health of the patient, his forces of immunity are usually victorious. *Surgery is seldom indicated* because each boil allows for autovaccination and, as in multiple foci from any bacteria, including tuberculosis, the disturbance of one focus may light up the other. Penicillin and the sulfonamides are extremely valuable. The use of blood transfusions are helpful. Locally, bacitracin is useful.

CARBUNCLE

Due to the anatomical peculiarities of the face, we may speak of carbuncle here as one variety and elsewhere on the body as another. The pathological changes are the same in both.

Body Carbuncle.—For practical purposes we may look upon a carbuncle as a group of boils, joined together by subcutaneous channels. Pus burrows down to the deep fascia along the columnae adiposae of the skin; then it burrows up again, establishing a large indurated area with multiple draining sinuses. Pain is severe and general constitutional symptoms are common. The surgical pathology is the same as that of a boil, multiplied many times as to infected "units." Carbuncle is seen more commonly in patients *without* associated disease, although it is true that in those whose general resistance is low or who have a debilitating disease, such as diabetes or chronic nephritis, the *proportion* who have carbuncles is higher than the incidence in the population as a whole. However, diabetes mellitus, for example, does not per se increase the susceptibility of the person with diabetes appreciably to pyogenic skin infections. It is not necessarily the really sick person who has a carbuncle. It is the one who constantly "picks" skin infections. Women have them on the face more often than men because they molest their faces more. Men have them more often on the neck. In tampering with them these people "make several blades of grass grow where one grew before." Likewise, if the carbuncles are incised too early by the surgeon, infected pus is spread over nonimmune areas, increasing the liability of more infection.

Treatment.—Heat is excellent after stasis has occurred; that is, usually, after two or three days. If used before this time, pain will be more severe, due to overdistention of the already dilated capillaries. We are inclined to do less surgery on boils and carbuncles than formerly. If a carbuncle appears on the arm, it is well to have the patient put the arm at rest in a sling, protect it with a bandage, apply heat, and let it alone. Some surgeons prefer moist heat (that is, hot hypertonic salt solution). Some also use glycerine and magnesium sulfate packs. Solutions must not be used

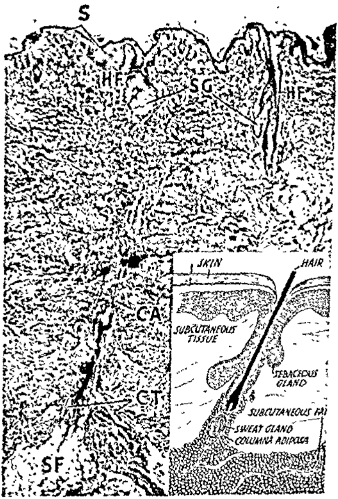

Fig. 26.—Photomicrograph and diagram illustrating the method of invasion of new zones in a carbuncle. The infection descends along the columns of Warren (columna adiposa), following the deep fascia (without invading it), and then ascends along other columns. *S*, skin *HF*, hair follicles; *SG*, sebaceous glands; *CA*, *columna adiposa*; *CT*, connective tissue, *SF*, subcutaneous fat.

continuously because the skin will become macerated. One should use moist packs for thirty minutes, then dry heat for two hours, etc. Carbuncles may be either excised or incised after localization has occurred. Both methods are useful. The latter is preferable in profoundly sick patients. The wound will usually heal without the necessity for skin graft. In either method the pyogenic membrane is not transcended.

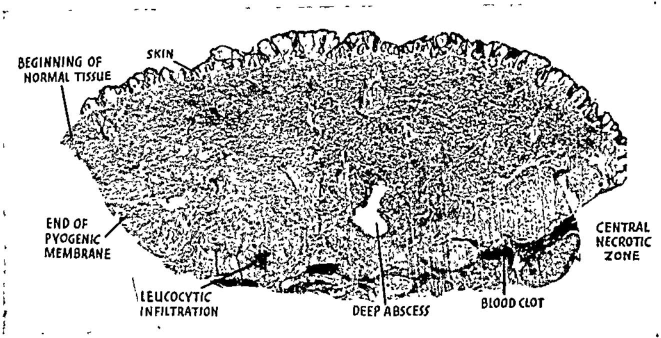

Fig. 27.—Photomicrograph of a carbuncle. On the right is the large central necrotic zone. As the infection spreads, new leucocytic barriers are formed until the entire area is ultimately walled in. (After Berman: Am. J. Surg. 40: 419, 1938.)

Facial Carbuncle.—Carbuncle of the face is a distinct entity because of local anatomical peculiarities. One of these is the blood supply, which communicates through the valveless angular and the superior ophthalmic veins with the cavernous sinus. *Another is the continuation of the platysma* (panniculus carnosus) into the face (as the muscles of expression) without any deep fascia. Since muscle tissue does not easily become infected unless

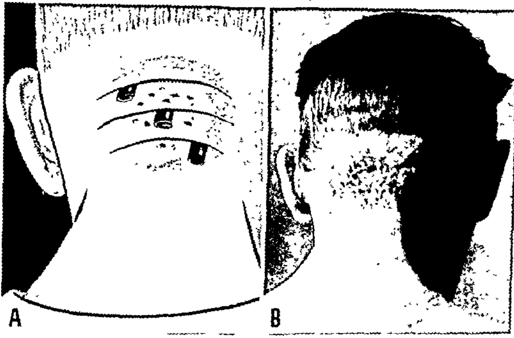

Fig. 28.—Treatment of carbuncle of the neck. *A.* Flaps may be fashioned more safely perhaps by what has come to be known as the "gridiron incision." This is a series of parallel lines with drains inserted beneath the double flaps. In this way each flap has a double blood supply coming from each side. Figure in part taken from Berman, J. K.: Carbuncle, Am. J. Sur., 40: 419-425, 1938.) *B.* Left half of carbuncle has been excised. Right half has been incised, leaving pedicle skin flaps. Note the accelerated healing on the right side due to viable flaps.

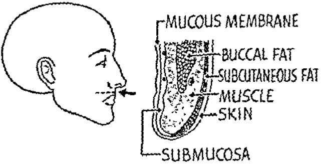

Fig. 29.—Diagram of a cross section of the face at the angle of the mouth. Six layers are shown: (1) skin, (2) fatty layer (traversed by external maxillary artery), (3) buccopharyngeal *fascia*, (4) *buccinator muscle*, (5) *submucous tissue* (*with buccal* glands), (6) *mucous* membrane.

The skin rests on the superficial fascia which is closely intermingled with the facial muscles. The buccal mucous membrane (within the mouth) rests *on* the submucous tissue. The muscles *of* expression are a continuation of the platysma (panniculus carnosus). Infections do *not involve the entire thickness of the cheek unless the muscles are* devitalized. Infection *may* involve the veins (spreading phlebitis) and may be carried by the veins in both directions, owing to the absence of valves.

Due to the laxity of the subcutaneous tissue, collections of *serum* or pus spread easily over the face, causing great swelling. The normal muscles act *as an effective* barrier and rarely do *skin infections involve the mucous membrane*. *The reverse* is also true.

devitalized, an infection in this region spreads laterally, by contiguity. This is especially true of the upper lip and around the nose, the danger zone of the face: septic thrombophlebitis may carry the infection into the brain, causing a fatal meningitis. Not uncommonly a patient will die of *a carbuncle developed by pulling hairs in the nose.*

Treatment.—Treatment should be conservative. X-ray treatment or hot moist packs of hypertonic salt solution may be used. The patient should be at rest in bed. Penicillin and the sulfonamides are given and bacitracin may be used locally. Excision is dangerous (because it may dislodge thrombi and spread the infection); it is also disfiguring. Incision may be necessary but usually is not. Some have advocated tying the angular vein. This does not stop the extension but instead encourages a spreading of the infection in surrounding tissue and in new collaterals that will form. Thrombi would be carried down into the external maxillary vein into the internal jugulars. The trauma of operation may dislodge these.

PARONYCHIA

There are many other examples of localized infections in addition to boils and carbuncles. A common one is *paronychia,* which means "near the nail" or "alongside of the nail" (eponychium). It is characterized by swelling and suppuration near the side of the nail. If it progresses, it may completely surround the base of the nail ("ring around" or "run around"). It results ordinarily from tearing a "hangnail," and though not usually serious, it is very painful and disconcerting. The surgical pathology of this condition is the same as that of other localized infections. The treatment is conservative. A hangnail should not be pulled or bitten off: it should be removed with sterile scissors. Should a paronychia develop, it must be unmolested until suppuration occurs. Then the eponychium is incised close to the nail and the pus evacuated. Too early incision tends to spread the infection. Incision after localization may be made through the thinned skin without anesthesia, painlessly. Soaking the finger in hot saline solution is a common though questionable practice. If overdone, the superficial layers of the skin become macerated. Infected blisters occur which may involve the entire finger. The blister must be opened promptly. If the infection has spread around the base of the nail, it becomes devitalized, acting as a foreign body and delaying healing. The nail should be removed in such cases. Locally, penicillin ointment or bacitracin ointment are beneficial.

Ingrown toenail is a common lesion occurring on the lateral side of the big toe. It is caused by tight shoes and by trimming the nail too short. The soft tissue (vallum unguis or nail wall) is pushed over the nail, which cuts into it, and the result is infection. Prevention consists of cutting the nail long and square, or flattening it with a nail file. Treatment in the early stages is palliative. Cotton, tin foil, or plastic material is introduced between the edges of the nail and the eponychium. In advanced

stages, the lateral edge of the nail and the granulation tissue must be incised. Sometimes the medial side of the nail bed is also involved (double ingrowing nail). The entire nail should be removed but not its root.

FELON

A *felon* is a deep-seated infection occurring in the distal anterior closed space of the finger, frequently involving the periosteum and the bone, with resulting osteomyelitis of the phalanx. It is excruciatingly painful and there is a tense, hyperemic swelling over the palmar side of the finger tip. Early lateral incision is the best treatment. Paradoxically enough, it is unnecessary to wait for localization. The anatomical closed space corresponds to the walled-in area of an abscess, and early drainage must be instituted if interference with the blood supply, because of intense pressure, is to be avoided. Infections in the mediastinum (mediastinitis), the fascial spaces of the neck (Ludwig's angina), and the ischiorectal space (ischiorectal abscess) are also exceptions to the rule, "Wait for localization." Should this occur, necrosis of bone, together with infection (osteomyelitis), will follow. A lateral incision is made, cutting across the connective tissue septa, and drainage is instituted with a small piece of rubber tissue. The finger should be immobilized in a splint. Should osteomyelitis result, sequestration will occur. It is best to wait until the dead bone separates before attempting its removal. Osteomyelitis results in a clubbed finger.

"Collar button" abscess of the palm usually occurs from infection at the site of a callus which has "cracked." This type of abscess usually localizes at the base of the finger after traveling behind the web, through the lumbrical canal, to the back of the hand. Roughly, the abscess resembles a collar button. The treatment is incision and drainage after localization.

DIFFUSE INFECTIONS OF THE HAND

Diffuse suppurative inflammation is usually caused by the streptococcus and has been called phlegmon or diffuse cellulitis.

Every infection of the skin is primarily a cellulitis; that is, an inflammation of cells, with a cellular response.

The dispersing type differs from the localized infections in its tendency to spread along fascial planes and involves veins and lymphatics. There is also more widespread destruction of tissue. Due to lymphatic communication there is a tendency for the infection to invade tendon sheaths, muscle septa, bursae, and joints. The exudate is serosanguineous, not frank pus. It contains relatively few polymorphonuclear leucocytes but has many blood cells. This is said to be due in part to the fibrinolytic and destructive action of the bacteria. Dilated and injured capillaries permit almost whole blood to leak through (although mostly plasma) and not just leucocytes which reach the area by diapedesis and ameboid move-

ment. Due to its widespread involvement there is a great loss of blood plasma, with a tendency for shock to develop. General symptoms are severe and the prognosis is less favorable than in localized infections. An injury, usually small, is followed in twenty-four hours by red streaks on the forearm. Then swellings or "kernels" occur under the arm. The streptococcus has penetrated the skin (first line of defense), invading the lymph vessels and producing a *lymphangitis;* this is followed by invasion and swelling of the axillary lymph glands, or *lymphadenitis* (second line of defense). At this stage there is a dull feeling with malaise. The temperature is 99.5 to 100° F.; there is a leucocytosis, indicating a blood stream invasion. These are the symptoms and signs of a streptococcic infection, with *tubular lymphangitis, lymphadenitis* and *beginning septicemia.*

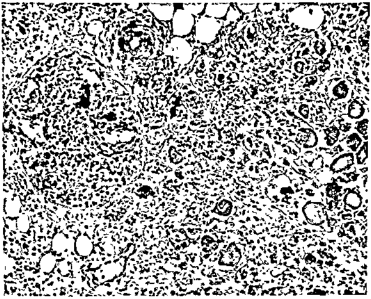

Fig. 30.—Diffuse cellulitis with septic thrombophlebitis. From a case of streptococcic cellulitis of the leg.

Progress and Treatment.—Ninety-five per cent of these patients get well if surgery is withheld. Should an incision be made across the infected tubular lymphatics the bacteria would find easy access to the surrounding tissue. Within seventy-two hours the forearm would be dark red because of a spreading cellulitis and the fever would be septic in type, indicating a general bacteriemia. For this reason it is unwise to cut across infected lymph vessels, *for the lymphatics are better able to cope with the streptococcus than the surrounding tissues.* Should localization with suppuration occur, incision may be indicated. Usually, however, this does not occur. The infection ends by resolution if treated by intermittent hot hypertonic soaks and complete rest and elevation of the arm. Should prompt resolution *not occur, penicillin and the sulfonamides* are used.

Infections of the Hand

If bacteria are *transplanted from one patient to another*, their virulence is increased. Should the surgeon prick or cut his finger, he must *go to the scrub room* and *scrub* his hand for eight minutes "by the clock"; this will encourage free bleeding and will open the wound, sterilizing it. *He must not* put iodine or strong antiseptics on it, for they will irritate the skin and will prematurely seal the wound. All wounds are contaminated but no wound becomes infected until six to eight hours have elapsed, unless a strong antiseptic has been used. Soap and water with scrubbing will remove the transient flora of bacteria in the surrounding skin. Large quantities of isotonic saline are used to irrigate the wound. Price has shown that the transient flora of the skin may contain any number of pathogenic bacteria, the resident flora few. Ordinary commercial soaps are not very good germicides against some bacteria of the skin, especially staphylococci. It is the vigorous scrubbing which mechanically removes the organisms as well as any foreign bodies present. Soap solutions allowed to dry on the skin *do not sterilize the skin surface. Price, in studies on* degerming, has shown that scrubbing the hands with brush, soap, and water *removes the transient flora of bacteria much more readily than the resident* flora. The rate of reduction is by about one-half for each six minutes of *scrubbing. Any antiseptic strong enough to kill bacteria is usually also* strong enough to injure the cells, and it is far better to have healthy cells, *even in the presence of some bacteria, than a temporarily sterile field with* damaged cells. Furthermore, antiseptics quickly lose their bactericidal power when mixed with body fluids, and the injury to cells plus the freshly incubated flora of bacteria under the dried serum actually increases infection. (See Chapter 16.)

Tendon Sheath and Fascial Space Infections

Trauma to the Hand Caused by Human and Animal Teeth.—Usually such trauma is inflicted by a bite but may result from fist-fights or blows on the knuckles in accidents. The most serious is that of the human bite or injury (marsus humanus). The bite of the cat, the camel, and monkey rank next according to Mason. The dog's teeth are clean if he lives in his normal environment and on his normal diet. House pets may harbor organisms in their mouths similar to those harbored by human beings.

The wounds are usually lacerated or contused with devitalization of fascia, ligament, tendon, cartilage, and bone. Tendons may retract, carrying the contaminating organisms deep into the sheaths, or fascial spaces may be directly penetrated. The organisms of the human mouth especially likely to produce a serious infection under such conditions are the nonhemolytic anaerobic streptococci, fusiform bacilli, and spirochetes. Meleney states he has never seen the two latter without the former organism in these infections. Needless to say, there are many other bacteria in the mouth, all of which may have a *synergistic action, thereby increasing their* virulence.

Teeth wounds of the trunk, face, and genitals are less serious. However, in two such wounds of the female breast the results were as severe as in the hand in our experience.

Treatment consists of prompt débridement and scrubbing with soap and water, leaving the wound wide open. Meleney recommends zinc peroxide in a creamy suspension locally. Sulfadiazine given by mouth and penicillin with streptomycin given intramuscularly is good prophylactic treatment. The hand and arm should be immobilized in a splint.

If a streptococcic infection of the hand spreads, it may involve tendon sheaths *(tenosynovitis)* or the fascial spaces of the hand *(facial space infection)*, producing widespread destruction of tissue and resulting in permanent deformity, loss of the arm, or even death. Hand infections require expert care and are treated by bed rest, blood transfusions, sulfanilamide or penicillin, timely incision followed by drainage, external heat, and early mobilization to prevent crippling.

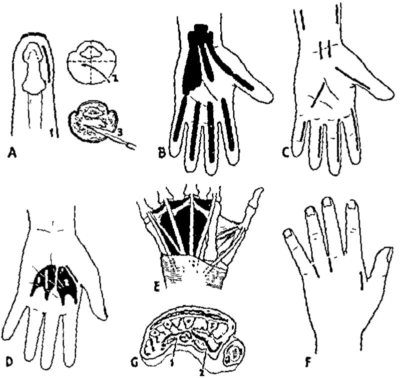

FIG. 31.—Diagrams illustrating anatomic and surgical considerations in hand infections (after Kanavel).

A. (1) The distal anterior closed space. Line shows site of incision. (2) and (3) Cross section of terminal phalanx, showing method of dividing fibrous septa. This avoids compression of digital arteries and subsequent necrosis of bone

B. The flexor tendon sheaths. Note the communication with the radial and ulnar bursae of the first and fifth sheaths, respectively, and the communication between the ulnar and radial bursae

C. Incisions for draining tendon sheaths and radial and ulnar bursae.

D. (1) The middle palmar space. (2) The thenar space. Place for incisions is indicated.

E. The dorsal subaponeurotic space

F. Place for drainage of the above and the thenar space (posterior approach).

G. Cross section of the hand showing the position of (1) the middle palmar space and (2) the thenar space The surgical approach on the palmar side is indicated.

Infections of the Hand

If bacteria are transplanted from one patient to another, their virulence is increased. Should the surgeon prick or cut his finger, he must go to the scrub room and scrub his hand for eight minutes "by the clock"; this will encourage free bleeding and will open the wound, sterilizing it. He must not put iodine or strong antiseptics on it, for they will irritate the skin and will prematurely seal the wound. All wounds are contaminated but no wound becomes infected until six to eight hours have elapsed, unless a strong antiseptic has been used. Soap and water with scrubbing will remove the transient flora of bacteria in the surrounding skin. Large quantities of isotonic saline are used to irrigate the wound. Price has shown that the transient flora of the skin may contain any number of pathogenic bacteria, the resident flora few. Ordinary commercial soaps are not very good germicides against some bacteria of the skin, especially staphylococci. It is the vigorous scrubbing which mechanically removes the organisms as well as any foreign bodies present. Soap solutions allowed to dry on the skin do not sterilize the skin surface. Price, in studies on degerming, has shown that scrubbing the hands with brush, soap, and water removes the transient flora of bacteria much more readily than the resident flora. The rate of reduction is by about one-half for each six minutes of scrubbing. Any antiseptic strong enough to kill bacteria is usually also strong enough to injure the cells, and it is far better to have healthy cells, even in the presence of some bacteria, than a temporarily sterile field with damaged cells. Furthermore, antiseptics quickly lose their bactericidal power when mixed with body fluids, and the injury to cells plus the freshly incubated flora of bacteria under the dried serum actually increases infection. (See Chapter 16.)

Tendon Sheath and Fascial Space Infections

Trauma to the Hand Caused by Human and Animal Teeth.—Usually such trauma is inflicted by a bite but may result from fist-fights or blows on the knuckles in accidents. The most serious is that of the human bite or injury (marsus humanus). The bite of the cat, the camel, and monkey rank next according to Mason. The dog's teeth are clean if he lives in his normal environment and on his normal diet. House pets may harbor organisms in their mouths similar to those harbored by human beings.

The wounds are usually lacerated or contused with devitalization of fascia, ligament, tendon, cartilage, and bone. Tendons may retract, carrying the contaminating organisms deep into the sheaths, or fascial spaces may be directly penetrated. The organisms of the human mouth especially likely to produce a serious infection under such conditions are the nonhemolytic anaerobic streptococci, fusiform bacilli, and spirochetes. Meleney states he has never seen the two latter without the former organism in these infections. Needless to say, there are many other bacteria in the mouth, all of which may have a synergistic action, thereby increasing their virulence.

which is intensified by *extension* of the finger from the protective flexed position. The proper site of incision is illustrated in Fig. 31.

Fascial spaces, as described by Kanavel, are as follows:

1. The *middle palmar space* lies on the interosseous muscles and metacarpal bones, with three extensions into lumbrical canals. This space extends laterally to the middle *metacarpal bone and proximally into the forearm* behind the ulnar bursa. Superficial to it are the flexor tendons, nerves, and vessels, which, in turn, lie beneath the palmar fascia.

2. The *thenar space* lies on the adductor pollicis muscle and adjoins the palmar space on its medial border. Roughly, it occupies the area of the thenar eminence. On dissection it is easy to tear through the delicate partition which separates the above spaces at their superior margin.

3. The *hypothenar spaces* are ill-defined, lying between muscles of this region.

4. The *dorsal subaponeurotic space* lies deep to the extensor tendons upon the posterior surface of the metacarpal bones.

5. The *dorsal subcutaneous space* lies just beneath the skin on the posterior aspect of the hand.

Treatment of Diffuse Infections of the Hand

From this anatomic discussion we may see that the proper management of a hand infection requires exact knowledge of the part and of the clinical manifestations of disease. Modern industry has, perhaps, brought hand injuries to the attention of physicians more than ever. Puncture wounds, compound fractures, and lacerations may be followed by diffuse inflammation. The connections with tendon sheaths have already been mentioned, and the usual association with lymphangitis makes diagnosis and treatment more difficult. The connections between spaces must also be understood, especially the likelihood of thenar space infections to involve the middle palmar space, and the probability of the latter to involve the ulnar bursa, and thence to spread to the radial bursa and down into the thumb. The middle palmar space infection presents a rather typical swelling in the palm and edema on the dorsum because of the fact that the lymphatics take the shortest route to the back of the hand and there is more or less *constriction to lymphatics about the wrist. There are pain and an associated* lymphangitis and lymphadenitis, with fever and leucocytosis. Treatment should be conservative until accurate diagnosis can be made. It is well to stress the possibilities of spread and ultimate crippling of the hand (due to adhesions of tendons and contractures) if there is delay. However, one cannot gainsay the fact that premature incision may have even worse results: it may cause a diffuse or spreading cellulitis involving the entire arm and necessitating amputation of the arm, or it may cause the death of the patient from septicemia. Therefore, if seen within six to eight hours after injury, wounds must be thoroughly scrubbed by the fractional sterilization method (see Chapter 16). Strong antiseptics should not be used. Wounds, depending on the type and age, are closed loosely or left open and covered with sterile gauze and the hand should be immobilized in a splint, over a soft pressure padding. Should infection occur,

Anatomy.—The tendon sheath is a lubricating device composed of two layers, visceral and parietal. The mesotendon is analogous to a mesentery. It is a double layer of synovial membrane and carries the blood supply to the tendon. Tendon sheaths are found only in the hands and feet and around the long tendon of the biceps brachii. The tendon sheaths (or mucous sheaths) of the flexor tendons of the fingers lie immediately subjacent to the skin, the superficial fascia, and the volar digital arteries and nerves. The fibrous sheaths which bind the flexor tendons to the volar surfaces of the phalanges and to the volar accessory ligaments of the metacarpophalangeal and interphalangeal joints cover these sheaths. The sheath of the little finger communicates directly with the ulnar bursa; that of the thumb, with the radial bursa behind the annular ligament (ligamentum carpi transversum). The sheaths of the fore, middle, and the ring fingers extend from the base of the distal phalanges into the palm, immediately proximal to the heads of the metacarpal bones. On either side, at the web, they are in contact with the lumbrical canals containing the lumbrical muscles and digital branches of the arteries and nerves. Since the radial and ulnar bursae communicate, infections may be spread as follows:

From thumb to radial bursa, into forearm, or into ulnar bursa

From index finger into proximal part, then rupture into lumbrical canals, and then into thenar fascial space

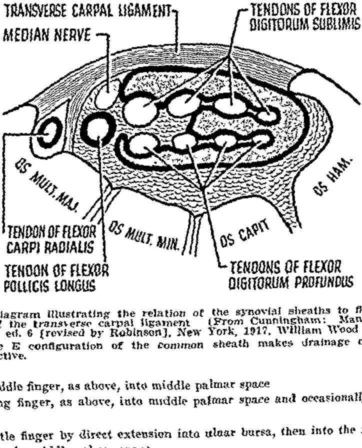

Fig. 32.—Diagram illustrating the relation of the synovial sheaths to flexor tendons at the level of the transverse carpal ligament. (From Cunningham: Manual of Practical Anatomy, ed. 6 [revised by Robinson], New York, 1917, William Wood & Co.)

The reverse E configuration of the common sheath makes drainage on the ulnar side more effective.

From middle finger, as above, into middle palmar space

From ring finger, as above, into middle palmar space and occasionally into ulnar bursa

From little finger by direct extension into ulnar bursa, then into the forearm, the radial bursa, or the middle palmar space

From any flexor sheath of the fingers into the metacarpophalangeal joints.

From radial or ulnar bursa into the wrist joint.

Incision should be made as soon as the diagnosis is made. This is made on the basis of pain or tenderness along the course of the sheath

necessary, and the sulfonamides by mouth and penicillin intramuscularly. Rarely local suppuration occurs; when it does, the area must be drained. In only two diseases involving infections of the lymphatics of the hand and arm do abscesses ordinarily occur along their course; namely, in tularemia and sporotrichosis, the former with lymph node involvement, the latter without. Rarely tuberculosis of the finger or hand may behave in a similar manner.

INJURIES TO THE HAND

Injuries to the hand require prompt treatment not only to prevent infection, but also to repair damaged tendons, nerves, muscles, and skin in an uninfected wound. First aid by factory nurses should consist of the *application of a tight sterile dressing. If necessary, a tourniquet may* be used.

If seen within eight to twelve hours under such preliminary management the wound may be thoroughly scrubbed with soap and water under aseptic technique. Other detergents such as mechanic soaps and carbon tetrachloride may be employed around the wound. These substances should be removed with alcohol, 70 per cent by volume. Ether may be used in *the wound to remove grease. Solid particles are mechanically removed* or picked out of the tissues. A careful débridement is then done. Nerves do not retract and are sutured with fine silk. Tendons do retract. They are brought together with fine silk as described in Chapter 3.

If the injured hand is seen after twenty-four to thirty-six hours or if strong antiseptics have been used, it is perhaps better not to attempt sterilization or primary suture of tendons and nerves. Such wounds are treated as infected and are left open without attempts at primary repair. Secondary suture may be done after five to six days. This may include the tendons and nerves, depending on the degree of contamination. (Chapters 16 and 21).

ERYSIPELAS

Erysipelas may be defined as an inflammation of the reticular lymphatics—a *reticular lymphangitis.* These lymphatics end blindly in the skin *and form a meshwork over the entire body. The disease is caused by* the *Streptococcus erysipelatis.* There are two principal kinds of erysipelas: that which is limited to the face *(facial erysipelas)* and that which is seen in other parts of the body *(cellulocutaneous erysipelas).*

Facial Erysipelas.—Facial erysipelas occurs in old and debilitated patients and in infants. It is characterized by a red zone which spreads across the nose onto both cheeks, assuming the shape of a butterfly. It has a sharp elevated margin (St. Anthony's fire). Locally there are burning and pain on the face. General symptoms are marked, the patient complaining of malaise with chills and fever. It is self-limited and does not involve the eyes but may involve the scalp. It does not form subcutaneous abscesses, due to the absence of deep fascia. *The treatment is supportive and consists*

dry or moist heat, with immobilization and the use of the sulfonamides and penicillin, may stem the tide of the invading organisms.

Careful observation will reveal the space or spaces involved if the foregoing treatment should fail after two or three days. By this time some local immunity has been established so that there is some *anatomical* as well as immunological localization. Under general anesthesia, with the use of tourniquet to ensure a bloodless field, incision is made into the infected space or spaces, and soft Penrose drains are inserted down to the space and not in it. Through-and-through drainage should not be used.

It is unwise to interfere surgically in the presence of lymphangitis, for the tubular lymphatics are better able to cope with the streptococcus than are the loose cellular tissues. The red streaks imply a perilymphangitis as well, and incision allows easy access of the infected lymph to the loose tissues.

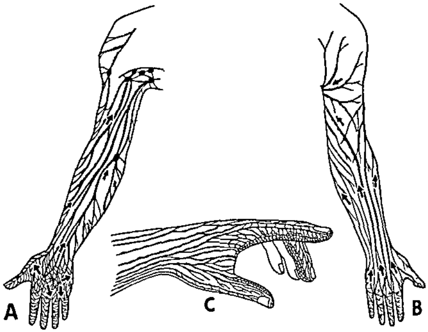

Fig. 33.—Diagram of the lymphatics of hand and arm (after Kanavel and Cunningham). *A.* The anterior surface. *B.* The posterior surface. *C.* The hand. The lymphatics in the hand take the shortest route to the dorsum. Drainage from the ulnar side is into the epitrochlear glands and from them into the axillary glands; from the radial side, directly into the axillary glands. The middle finger may drain directly into the supraclavicular group.

Koch has emphasized Kanavel's teaching of the anatomy of hand lymphatics. They take the shortest course to the back of the hand (which is swollen no matter where the *infection is*), *travel along the flexor surface* of the forearm where those from the ulnar side pass into the epitrochlear nodes, and then reappear and continue into the axillary nodes; those from the *radial side empty directly into* the axillary nodes; those from the forefinger and thumb may empty into the supraclavicular nodes. The treatment is rest to the part by splint (delimiting lymphatic absorption and *allowing* lymphatic plugging, which favors the establishment of local immunity), bed rest of the patient, ample fluid and food, transfusion, if

necessary, and the sulfonamides by mouth and penicillin intramuscularly. Rarely local suppuration occurs; when it does, the area must be drained. *In only two diseases involving infections of the lymphatics of the hand and arm do abscesses ordinarily occur along their course;* namely, in tularemia and sporotrichosis, the former with lymph node involvement, the latter without. *Rarely tuberculosis of the finger or hand may behave in a similar manner.*

INJURIES TO THE HAND

Injuries to the hand require prompt treatment not only to prevent infection, but also to repair damaged tendons, nerves, muscles, and skin in an uninfected wound. *First aid by factory nurses should consist of the application of a tight sterile dressing.* If necessary, a tourniquet may be used.

If seen within eight to twelve hours under such preliminary management the wound may be thoroughly scrubbed with soap and water under aseptic technique. Other detergents such as mechanic soaps and carbon tetrachloride may be employed around the wound. These substances should be removed with alcohol, 70 per cent by volume. Ether may be used in the wound to remove grease. Solid particles are mechanically removed or picked out of the tissues. A careful débridement is then done. Nerves do not retract and are sutured with fine silk. Tendons do retract. They are brought together with fine silk as described in Chapter 3.

If the injured hand is seen after twenty-four to thirty-six hours or if strong antiseptics have been used, it is perhaps better not to attempt sterilization or primary suture of tendons and nerves. Such wounds are treated as infected and are left open without attempts at primary repair. Secondary suture may be done after five to six days. This may include the tendons and nerves, depending on the degree of contamination. (Chapters 16 and 21).

ERYSIPELAS

Erysipelas may be defined as an inflammation of the reticular lymphatics—a reticular lymphangitis. These lymphatics end blindly in the skin and form a meshwork over the entire body. The disease is caused by the *Streptococcus erysipelatis. There are two principal kinds of erysipelas:* that which is limited to the face *(facial erysipelas)* and that which is seen in other parts of the body *(cellulocutaneous erysipelas).*

Facial Erysipelas.—*Facial erysipelas occurs in old and debilitated* patients and in infants. It is characterized by a red zone which spreads across the nose onto both cheeks, assuming the shape of a butterfly. It has a sharp elevated *margin* (St. Anthony's fire). *Locally there are burning and pain on the face* General symptoms are marked, the patient complaining of malaise with chills and fever. It is self-limited and does not involve the eyes but may involve the scalp. It *does not form subcutaneous abscesses,* due to the absence of deep fascia. The *treatment* is supportive and consists

chiefly of sedation, relief of pain, ample fluid intake, and the sulfonamides. Penicillin is efficacious and may be used alone or with the sulfonamides.

Cellulocutaneous Erysipelas.—Cellulocutaneous erysipelas usually enters through a wound and may be anywhere except on the face. It starts in the reticular lymphatics, then spreads down to the fascia by the connecting lymphatics, and is carried along the fascia by the tubular lymphatics. It is not self-limited and tends to spread along the deep fascia, lifting the overlying skin, which may become devitalized. It tends to form local areas of suppuration. General symptoms are marked. The treatment consists of rest or immobilization of the part, hot hypertonic salt packs, incision and drainage over all fluctuant areas as they occur, the sulfonamides internally, and penicillin.

Miscellaneous Varieties of Erysipelas.—*In this group may be included* various clinical types such as (1) migratory, (2) dermatophytid, (3) lymphangitic, (4) recurrent of the lower legs, (5) recurrent varicose vein, eczematoid, and varicose ulcer. Perhaps other clinical varieties may be enumerated which are subdivisions of the foregoing and partake of the same clinical features as well as causative agents.

Migratory erysipelas spreads over various areas of the body in waves. Sometimes all of the cutaneous surface, including the face and scalp, is involved in a succession of episodes. The disease is seen on the lower extremities in association with dermatophytosis of the feet. Some investigators believe that in such cases the inflammation is allergic in nature or a *dermatophytid*. A more reasonable explanation is that the streptococci enter through the fungus lesions, producing erysipelas with or without *lymphangitis*, usually the latter. Sometimes the *recurrent variety of the lower legs* is due to *varicose vein stasis* and *eczema* with minor abrasions or an *ulcer* as the atrium of repeated infection. We have seen patients in whom we could establish no demonstrable cause for the repeated attacks. Even the cellulocutaneous type may be encountered in the legs without apparent cause, although some trauma is probably causative. In all varieties the symptoms may be mild or severe, with chills and fever and high leucocytosis. Sulfanilamide is specific and should be used in doses of 1 to 2 Gm. every four hours until there is a 6 to 8 mg. blood concentration. Penicillin, 50,000 units, every six hours intramuscularly or penicillin in oil, 300,000 units daily, may be employed with or without sulfonamides. In all cases attention must be given to the associated condition.

Erysipeloid is so named because it resembles erysipelas. It is usually seen on the hands of those who handle meat, fish, and cheese, especially in the summer months. Clinically it begins with a small erythematous purplish area which itches. Soon it spreads slowly up the arms. There are few general symptoms. The disease is self-limited. It is thought to be related to a disease in swine (*Erysipelothrix rhusiopathiae*). An immune serum is available and is effective in swine erysipelas and in erysipeloid.

Treatment of Diffuse Inflammations.—This may be briefly summarized as follows:

I. General treatment

1. Rest to the part (in an extremity, splinting)
2. Rest in bed for the patient
3. Sulfanilamide until the concentration in the blood reaches 8 to 10 mg. per 100 c.c. or penicillin, 100,000 units, every three hours intramuscularly until favorable effects are secured
4. Adequate fluid and caloric intake (glucose)
5. Transfusion of blood

The citrate method of blood transfusion is a universal and well-standardized procedure. For technique and quantity employed, see Chapter 13. The amount used in infections will depend upon (a) the patient's ability to take and metabolize food, (b) the rate of blood destruction by the invading organisms as determined by erythrocyte counts and hematocrit, (c) the body's response and its need for more blood, (d) the age and weight of the patient. Plasma may be needed rather than whole blood due to its loss through permeable capillaries and also because of the lack of adequate protein intake and production as well as its excessive loss resulting in hypoproteinemia. It is better to use fresh blood and fresh plasma rather than the stored products because of the higher antibody content in the former (see Chapter 13).

Some observers have advocated the use of immune blood from patients who have recovered recently from like infections and whose blood is full of immune bodies. Others have even advocated the injection of an attenuated antigen into a donor and then later (after six to eight days) using his blood.

II. Local treatment

1. Wait for localization, with abscess formation, before instituting surgery
2. Apply dry heat either by hot pad, water bottle, or heat cradle

The latter is best because it does not traumatize, keeps an equal temperature, provides for moisture (humidifier may be made with a small trough in the cradle), and does not disturb the patient. Recently, cold has been employed in the treatment in infections. This is not good treatment for the reasons given (see Chapters 5, 6, 14, and 20). It is excellent treatment if amputation is indicated as a preliminary preparation.

3. In spreading cellulitis, when necessary as a last resort, amputation may be required.

POSTOPERATIVE INFECTIONS

Postoperative infections are not common after "clean" operations or in uninfected cases. However, with the increasing use of nonabsorbable sutures in surgery, complete asepsis is desirable, for any infection may pro-

duce a long period of disability. The source of the infection may be (1) inadequate masking, (2) upper respiratory infections in the operating team with sneezing and coughing, (3) insufficient scrubbing of hands, (4) breaks in aseptic technique (letting hands down after scrubbing, touching sheets, etc.), (5) contaminated suture material, (6) contamination from bowel or abscess during operation, (7) growth of bacteria in wound during a long operation, (8) the bacteria which are present in all tissues. The prevention lies in eradicating the source, if possible, and in avoiding infection from residual bacteria in the skin, muscle, etc., by the most gentle handling and protection of these tissues. To accomplish this there should be (1) minimal trauma, (2) accurate hemostasis (by the use of small hemostats, accurately applied) in order to prevent blood clots, and necrosis of tissue through taking too large "bites" of tissue (both blood clots and necrosed tissue act as foreign bodies and make excellent culture media), (3) protection of the wound margins by gauze sponges, (4) gentle retraction of the margins of the wound, (5) careful flushing of the wound with physiological saline at the conclusion of the operation, (6) débridement of any fat tissue which may have become devitalized, (7) careful loose approximation of the edges of the wound, and (8) postoperative rest without disturbance of the wound until local immunity has been established (eight days) unless local pain, excessive drainage, or fever demands investigation.

Accidental wounds are discussed in Chapter 16. They should be sterilized and left open or drained.

All potentially infected wounds, such as amputations for gangrene or for spreading cellulitis, should have no flaps (guillotine), and if closed at all should be closed very loosely, with drainage.

Rarely gas gangrene occurs after such amputations. This has been attributed to anaerobic bacteria which are normally present in muscle and which take on growth when it is devitalized. Such bacteria are usually harmless. They are probably made virulent by associated streptococcic infection.

Fever occurring immediately after an operation is due to a mild infection in the wound or at the site of the operation. A rise in temperature occurring after two or three days is also usually due to infection in the wound, although in some cases it may be due to such conditions as phlebitis (femoral, or at the site of operation), thrombophlebitis with pulmonary infarcts, massive collapse of the lung, urinary infections, parotitis, or upper respiratory infections.

A "stitch abscess" is usually caused by the staphylococcus albus. It is not the common type of postoperative infection. The infection extends to the superficial fascia. The patient does not complain of unusual pain. There is no, or very little, rise in temperature. Removal of the stitch supplies drainage and results in early recovery.

After infected cases, such as suppurating appendicitis or spreading peritonitis, the *colon bacillus (Escherichia coli)* may cause a wound infection. There is not much pain but the temperature is elevated. Inspection

of the wound may reveal little. Probing evacuates brown, foul-smelling pus, *which contains air bubbles. Often there is fascial sloughing.* Drainage with removal of sloughs results in recovery, which is often extremely slow. After surgery the colon bacillus may give rise to infections in the abdominal wall which are difficult to diagnose. This is due to the fact that air in a cavity under an incision may be mistaken for a loop of bowel. X-ray examination is of great value. Then aspiration by syringe and needle provide the diagnosis.

Dehiscence of postoperative abdominal wounds should be mentioned here because a diffuse infection in the incision may be the cause. Our experience has been that the infection is only a contributory factor. Delays in wound healing have been adequately discussed in Chapter 3. The factors mentioned apply to postoperative abdominal wounds as well as to others.

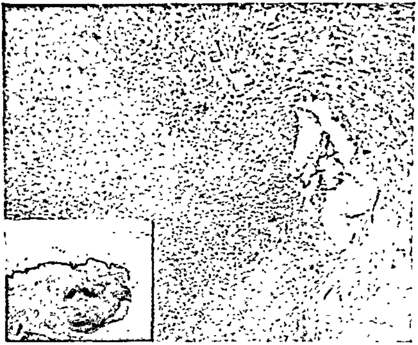

Fig. 34.—Stitch abscess (human). The low power shows reaction occurring about the catgut stitch and the sinus opening in the skin at the point of insertion. The high power shows the stitch (on right), with inflammatory reaction about it. Pus is seen on the upper left.

Usually the separation of a wound is due to a faulty closure (see Chapter 20). There are two outstanding exceptions: incisions which are drained in chemical peritonitis (acute hemorrhagic pancreatitis and perforated peptic ulcer) and operative wounds in very badly debilitated and cachectic patients. In the former, there is actual digestion of sutures (if absorbable) and granulation tissue; infection does not play a part. Therefore, if drainage is indicated, it is done through a "stab" wound. In the latter there is infection but it is usually a secondary factor in an unhealed wound. Adequate pre- and postoperative care may preclude this (see Chapter 2).

Streptococcus pyogenes, especially in combination with *Staphylococcus aureus* (symbiosis), may cause widespread destruction of the abdominal wall. Sometimes gangrene of the abdominal wall results. The cause is the "soil" rather than the "seed"; that is, poor resistance in a very sick patient rather than the unusual character of the bacteria. These infections are often fatal. Free drainage, or "unroofing" of the infected area, is required. Blood transfusions to improve the patient and his resistance are given. Sulfonamides or preferably penicillin may be given, and locally zinc peroxide is useful (Meleney).

Complications of suppurative inflammation include (1) *thrombosis*, (2) *phlebitis* and *thrombophlebitis*, (3) *pulmonary infarction*, (4) *septicemia*, and (5) *toxemia*, and (6) *pyemia*.

Thrombosis, Phlebitis, and Thrombophlebitis.—We have seen that infected thrombi are present in the small capillaries around localizing infections and that although they are usually absorbed, they may be dislodged by the pressure of the accumulating pus and carried by the blood stream to the lungs. In spreading or diffuse inflammations, larger vessels may be involved (thrombophlebitis) and may give rise to emboli. Should this occur in the portal system (pylephlebitis), the emboli would be carried to the liver. In the rectum, either the portal system or the systemic veins may be involved. Infected thrombi are perhaps the greatest hazard of suppurative inflammation. (See Chapter 17.)

Pulmonary Infarction.—The word infarct is derived from *infarcire*, meaning to stuff in. The term has been used to include any tissue destruction from an area of local necrosis to gangrene of the bowel or an extremity. The word was chosen because the collateral vessels about an occluded artery or vein quickly fill with blood and are literally stuffed with red cells. In common parlance it means an interruption of the blood supply of a part with subsequent more or less characteristic changes in the deprived tissues. The obstructed blood vessel may be an artery or a vein. Although it is far more common in the former, the latter is seen in mesenteric thrombosis or a similar state produced by volvulus, strangulation, twisted organ cyst, etc.

The death of tissue is due essentially to a lack of oxygen. Therefore, if the collateral circulation is quickly and adequately formed, infarction may be avoided. If delayed, tissue changes occur even though later, the blood supply with its nutritive material and crystalloids is ample and the waste products are removed.

Karsner believes that infarction in the lung is possible only when there is passive congestion, which may be due to heart disease, other infarcts, pleural effusion, etc., because ordinarily the collateral circulation is so rich that local anoxia is not present long enough to cause the death of cells. It is known, however, that infarcts following pulmonary embolism occur in surgical and medical cases without heart failure (60 per cent), although more commonly in cardiac patients (90 per cent). Perhaps the decrease in vis a tergo caused by the embolus produces its own passive congestion or

the stasis may be a part of the decreased respiratory excursions due to complete bed rest or abdominal distention.

The difference between white and red infarcts is not always due to the type organ involved, that is, white, if the infarction occurs in organs with so-called end arteries, and otherwise red. In dense organs collateral circulation will be less; therefore, the infarct is more apt to be white. Although either white or red infarcts do occur in the spleen or in the lung, both varieties *may be present simultaneously*. *Usually infarcts are white when* they occur in organs with so-called end arteries, as in the kidney, spleen, retina, and basal ganglia of the brain. In organs with a double blood supply infarcts are usually red. This is seen in the lung and liver. The wedge shape which is supposed to be characteristic is due to the fanlike arrangement of the vasculature; this is not always the case.

Abnormal Physiology in Infarction.—Infarcts are not *anemic* if any collaterals are present even though they are *anoxemic*. Therefore, the term anemic infarct should be dropped. Immediately after an embolus there is a peripheral vasospasm although small particles of a thromboembolus may find their way into the arterioles and capillaries of the lung. Then neighboring capillaries dilate (if present) and are stuffed with red cells. Some of these vessels rupture and the area is red. If coagulation necrosis sets in before this rhexis of vessels or if there are few collaterals, the infarct is white.

Anoxemia is the key to the whole local process and causes the death of cells. Coagulation necrosis has been compared by MacCallum to the ruins of Pompeii. The cells, though retaining their outlines, are dead, coagulated intra- and extracellularly. The coagulation is said to be due to a ferment or coagulable fluids from surrounding area and to fibrin.

The sequence of events are therefore local anoxemia, vasospasm, or blockade by small embolic particles, hyperemia (if collaterals are present), loss of plasma, coagulation of cells, cloudy swelling of cells in two hours, and necrosis of parenchymatous cells in forty-eight hours. Connective tissue cells survive longer and may be spared. Dead cells and pigments(decolorization) are removed by macrophages and reticuloendothelial cells. Granulation tissue forms as in any wound. Then healing takes place by second intention with ultimate cicatrization.

If the embolus is infected, a pulmonary abscess may result. Not all pulmonary abscesses are due to septic emboli; some result from aspiration of infected vomitus or mucus during anesthesia. (See Chapter 19.) It is well known, however, that the incidence of pulmonary embolism is as great following local as following general anesthesia, and, according to some, it is three times more common following spinal anesthesia. The reason was thought to be the lowered blood pressure due to dilation of the capillaries and to the longer period of immobility, resulting in stasis in the veins, followed by phlebothrombosis. However, the incidence of pulmonary abscess in such cases is extremely low (Chapter 17).

Streptococcus pyogenes, especially in combination with *Staphylococcus aureus* (symbiosis), may cause widespread destruction of the abdominal wall. Sometimes gangrene of the abdominal wall results. The cause is the "soil" rather than the "seed"; that is, poor resistance in a very sick patient rather than the unusual character of the bacteria. These infections are often fatal. Free drainage, or "unroofing" of the infected area, is required. Blood transfusions to improve the patient and his resistance are given. Sulfonamides or preferably penicillin may be given, and locally zinc peroxide is useful (Meleney).

Complications of suppurative inflammation include (1) *thrombosis*, (2) *phlebitis* and *thrombophlebitis*, (3) *pulmonary infarction*, (4) *septicemia*, and (5) *toxemia*, and (6) *pyemia*.

Thrombosis, Phlebitis, and Thrombophlebitis.—We have seen that infected thrombi are present in the small capillaries around localizing infections and that although they are usually absorbed, they may be dislodged by the pressure of the accumulating pus and carried by the blood stream to the lungs. In spreading or diffuse inflammations, larger vessels may be involved (thrombophlebitis) and may give rise to emboli. Should this occur in the portal system (pylephlebitis), the emboli would be carried to the liver. In the rectum, either the portal system or the systemic veins may be involved. Infected thrombi are perhaps the greatest hazard of suppurative inflammation. (See Chapter 17.)

Pulmonary Infarction.—The word infarct is derived from *infarcire*, meaning to stuff in. The term has been used to include any tissue destruction from an area of local necrosis to gangrene of the bowel or an extremity. The word was chosen because the collateral vessels about an occluded artery or vein quickly fill with blood and are literally stuffed with red cells. In common parlance it means an interruption of the blood supply of a part with subsequent more or less characteristic changes in the deprived tissues. The obstructed blood vessel may be an artery or a vein. Although it is far more common in the former, the latter is seen in mesenteric thrombosis or a similar state produced by volvulus, strangulation, twisted organ cyst, etc.

The death of tissue is due essentially to a lack of oxygen. Therefore, if the collateral circulation is quickly and adequately formed, infarction may be avoided. If delayed, tissue changes occur even though later, the blood supply with its nutritive material and crystalloids is ample and the waste products are removed.

Karsner believes that infarction in the lung is possible only when there is passive congestion, which may be due to heart disease, other infarcts, pleural effusion, etc., because ordinarily the collateral circulation is so rich that local anoxia is not present long enough to cause the death of cells. It is known, however, that infarcts following pulmonary embolism occur in surgical and medical cases without heart failure (60 per cent), although more commonly in cardiac patients (90 per cent). Perhaps the decrease in vis a tergo caused by the embolus produces its own passive congestion or

which are useful in some chronic infections, although this is open to question (staphylococcic, mixed, tuberculous).

2. Drugs: sulfonamides, penicillin, streptomycin, aureomycin, Choromycetin.

3. Attention to body requirements: oxygen, water balance, blood, and plasma.

4. Physiotherapy (heat) and radiotherapy (early in staphylococcic infections).

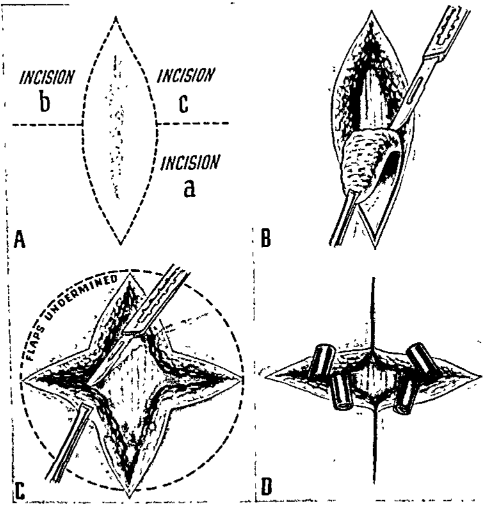

Fig. 35.—Pilonidal sinus. *A.* Lines of excision and incision in the removal of pilonidal sinuses and their ramifications. *B.* Excision of the primary sinuses. *C.* Undermining of flaps and excision of all subcutaneous channels. *D* Partial closure with drainage in infected cases. The wound edges are loosely approximated by subcutaneous absorbable sutures so that subsequent swelling will not produce an ischemia of the suture lines. Other methods of excision are shown in chapter 6 (From Berman, J. K., Am J. Sur. 70: 360-363, 1945.)

Aphorisms.—If the primary focus in an acute septicemia can be eradicated, the patient will probably recover. This is as true of appendicitis as it is of a spreading cellulitis of the hand and arm. In the former, the treatment is appendectomy, in the latter, incision and drainage after

Septicemia (Bacteriemia).—This is a state in which bacteria are found in the blood, a tissue in which they are not normally contained. However, the mere presence of bacteria in the blood stream does not indicate that there is an infection. The bacteria may belong to a strain that is perfectly harmless. If a patient has tetanus or diphtheria, there will be toxins in the blood; this is known as a *toxemia*. The term septicemia is used loosely to include both bacteriemia and toxemia. Formerly the term septicemia was used to indicate the presence of any putrefactive product in the blood; that was before the advent of Pasteur and Lister. A patient with a high fever and repeated negative blood cultures probably has a severe bacterial toxemia. If the blood cultures are positive he is said to have a bacteriemia. A positive blood culture is not invariably obtained when there is a bacteriemia, for the bacteria may be lodged in the reticulo-endothelial cells and the culture may be negative in the presence of severe general infection. The end stage of a bacteriemia will usually yield a positive culture because the reticulo-endothelial system is blocked, humoral immunity is low, and the blood stream is teeming with microorganisms.

Toxemia.—Toxemia has been very loosely applied to mean toxins in the blood from bacteria (tetanus, diphtheria, botulinus, as well as pyogenic organisms), chemical substances introduced (alcohol cyanide), the products of abnormal metabolism (beta-hydroxybutyric and acetoacetic acid), and hypothetical or ill-defined so-called toxins which are present in a great variety of chemical conditions. We speak of thyrotoxicosis in which no toxin has been identified. The toxemia of burns, crush syndrome, intestinal obstruction, and pregnancy may be due to a variety of causes such as dehydration, starvation, hemoconcentration, infection, or anoxemia.

In toxemia of pregnancy such a combination could be causative. If fibrinogen is injected into the portal vein of experimental animals, a patchy necrosis of the liver occurs. This same type of hepatic change is seen at times in severe burns and in the toxemia of pregnancy. In the latter there may be an amniotitis or chorionitis with local loss of fluid into the amnion, producing a polyhydramnios. The continued loss of fluid would cause a hemoconcentration, stagnant anoxemia, patchy necrosis in the brain, kidney, and liver due to the anoxemia, and local thrombus formation. Edema may be due to the leaky capillaries which are made so by anoxemia or to intracellular edema due to the great affinity of tissue cells for sodium for osmotic reasons. The high blood pressure may be a compensatory mechanism to increase kidney filtration. There is no proof for this theory which is given to illustrate what may be the cause of so-called toxemia.

Pyemia.—Pyemia literally means "pus in the blood." Its modern usage implies a septicemia (or bacteriemia) with multiple abscess formation such as seen in multiple furunculosis, multiple osteomyelitis, etc. The treatment of a bacteriemia, toxemia, or pyemia is first the removal of its cause if possible, as will be discussed in the next paragraph. However, there are many important adjuvants which may be used. They are:

1. Biologicals such as antitoxins (tetanus, diphtheria, staphylococcic which neutralizes the exotoxin), toxoids (tetanus, staphylococcic), vaccines

The general ability of a patient to take and metabolize food is a good sign. *It is often the "soil" rather than the "seed" which is at fault.* All laws of prognosis are relative because life itself is relative.

Sequelae of Pyogenic Infection.—

Sinus and Fistula.—A sinus is an abnormal opening in the skin which ends blindly in the tissues and usually discharges purulent material. The most common cause of a sinus is a foreign body; a second common cause is the persistence of an embryonic cavity.

Foreign Bodies.—In children with osteomyelitis where a piece of dead bone (sequestrum) is left, a draining sinus will continue until it is removed or extruded. Because it may act as a foreign body, unabsorbable suture material, such as silk or linen, should not be used in the presence of infections. It is possible for a foreign body to remain in the tissues without sinus formation. If the wound is sterile, or the operation is a clean one, the surgeon may elect to use only silk, as in hernia repair or thyroidectomy. Bullets or pieces of metal may remain in tissues without much reaction and may be completely walled in by fibrous tissue if no infection is present.

Embryonic Cavities.—Pilonidal sinus is perhaps the most common. (*Pilo-* means hair; *nidal* means nest—that is, nest of hair). It is caused by a congenital defect in the gluteal cleft posterior to the rectum. It is lined with epithelium and may extend down to the sacrum. It contains hair and cellular debris and therefore it is caused by embryonic cavity and foreign bodies as well. Since infection is common, it becomes painfully inflamed or it may be discovered because of a local irritation (so-called "jeep disease") excoriation, or abscess. The only treatment is complete eradication.

The branchial clefts should close before birth. Often they remain as small sinuses which are anterior to the sternocleidomastoid muscle in the neck. They become infected and will drain until the epithelium-lined cavity is removed. They may also persist as a fistula or a cyst.

A fistula is an abnormal opening from a hollow viscus to the outside, from one hollow viscus to another, or from a secreting gland to the outside or between blood vessels. (Examples—(1) From a hollow viscus to the outside: complete *fistula in ano* (from the rectum to the perineum); *urinary* fistula (from the urinary bladder to the outside); *fecal* fistula (from the bowel to the outside); *biliary* fistula (gall bladder or common duct to the outside). (2) From one hollow viscus to another: *vesico-intestinal* fistula (a fistula between the bladder and intestine); vesico-uterine (a fistula between the bladder and the uterus); *vesico-vaginal fistula* (this is, in a sense, from one hollow viscus to another and is also from a hollow viscus to the outside) Sometimes the surgeon deliberately makes a fistula to the outside (cholecystostomy, enterostomy) for temporary drainage or from one hollow viscus to another (gastroenterostomy or cholecystogastrostomy) for permanent short-circuiting. (3) Secreting gland to the outside: *salivary* fistula (saliva drains onto the outside of the cheek from the parotid gland due to blockage of the parotid duct or Stensen's duct); sometimes

localization. Should no localization occur in a spreading cellulitis, amputation may be necessary to save the patient's life. Unfortunately the eradication of an acute focus may be impossible. For example, in septic abortion, although the focus is in the uterus, the veins also are infected (thromophlebitis): any attempt at surgical removal would undoubtedly release septic emboli. Therefore, in all cases where the eradication of an acute focus is impossible, the patient should receive blood transfusions, antibiotics, and chemotherapeutic agents, and he should be kept at rest in bed. Later the focus may be eradicated.

A patient who survives the initial onslaught (three to four days) will probably recover.

Fig. 36.—Pilonidal sinus. The low power shows the epithelium-lined sinus and the reaction in the surrounding tissue, the high power shows the hair shafts and the foreign body reaction in the tissue about them.

Patients with jaundice (due to toxic hemolysis, or liver abscess caused by septic pyelephlebitis of the portal system) have a bad prognosis.

Terminal fatalities in pneumonia and in typhoid fever due to septicemia. The consolidated lobe in the former and the enlarged Peyer's patches in the latter are local manifestations of these infections.

The danger of septic emboli is perhaps the greatest hazard in infection. This danger may be partially obviated by rest to the part, prevention of trauma, ample fluid, blood transfusion, and well-timed atraumatic surgery (see Chapter 11).

Every disease with fever should be considered as a toxemia or a bacteriemia and its cause or causes carefully sought. Exceptions are given in Chapter 4.

aseptic, atraumatic surgery in preventing postoperative infections and they do not cure such infections without the aid of proper well-timed surgical management and, above all, the natural response of the body.

First we shall review the general concept of antimicrobic agents and their mode of actions. Then we may list the drugs available, their indications, their contraindications, and their toxic effects.

Practically all antibacterial agents are said to have either a bacteriostatic or bacteriocidal effect. Although it is desirable to annihilate the invading organisms, it is undesirable to injure tissue cells. Bacteriocidal agents are usually antiseptics which are gross protoplasmic poisons. They destroy the metabolic and especially the **catabolic mechanism** of the living cell whether it be bacterial or tissue.

As we have previously avowed, the "age of antiseptics" has joined the age of "boiling oil and hot irons" in the treatment of wounds.

Bacteriostatic agents are the chemotherapeutic drugs. Most of them have a very selective effect on anabolism, catabolism, oxygen consumption ability (sulfonamide), or cellular division (penicillin). Some also have similar effects on certain tissue cells (gramicidin and tyrocidine).

Enzymes (such as lysozyme) act in still another way. They are said to destroy certain structural components of an organism, causing lysis and death, or by digesting away the capsule they may make an organism susceptible to phagocytosis. Thus there have been obtained from saprophytic microorganisms and also from leech extract, enzymes capable of hydrolyzing capsular polysaccharides of pneumococci and streptococci.

Lastly the enzymes may affect end products of bacteria, rendering them toxic for the microorganisms.

Theories as to the Mode of Action of Sulfonamides

There are many theories as to the mode of sulfonamide action. In general it is thought that these drugs produce an environment which is unfavorable for bacterial growth. This is what nature does when she produces a local immunity. The normal protein molecule is not readily utilized by bacteria. They therefore release an enzyme or various enzymes which produce proteolysis. One of the chemical substances which is essential to bacterial nutrition is para-aminobenzoic acid which, in turn, closely resembles the sulfonamide molecule. If, now, a sufficient number of sulfonamide molecules are present, their bacterial enzymes may be prevented from properly engaging the para-aminobenzoic acid and thus be effectively deprived of their nutrition. This is known as competitive enzyme inhibition (Lockwood). If we may use X to denote the bacterial enzyme, then para-aminobenzoic acid plus X equals a metabolite suitable directly or indirectly for bacterial growth. If now we substitute the sulfonamide molecule we have: Sulfonamide plus X equals inactive substance. The law of mass action implies that chemical action is determined by the respective amounts of the substances acting in unit volume or by the degree of the concentrations present. If sulfonamides

combined types of fistula are found. (4) Blood vessels: *arteriovenous* (traumatic or congenital) arterioarterial as in patent ductus arteriosis.

Laws of Fistulae.—If the normal channel is open, the artificial channel will close, unless the fistula is one of the following five types: (1) Tuberculous fistula. (2) Fistula due to a mycotic infection (any disease caused by a fungus). (3) Fistula resulting from malignancy. (4) Purposeful fistula (if a tube is anchored into the intestine, as is done in an enterostomy, the fistula will remain open as long as the tube is in place). (5) Fistula in which the mucous membrane has grown to the skin, or to another organ through disease or surgery. (6) Endothelial lined tubes between blood vessels. For example, if a cholecystostomy is performed, a tube is introduced in the gall bladder to cause bile to drain to the outside. This is a biliary fistula. Now, if this does not heal after the removal of the tube and bile continues to drain, one of five things is at fault: (a) There is a stone or stricture, or occluding pressure on, or in, the common duct, so that the bile cannot get from the common duct into the intestine (normal channel is not open). (b) It is a tuberculous fistula. (c) It is a mycotic infection. (4) It is caused by a malignant growth, such as carcinoma. (5) The mucous membrane of the gall bladder has grown to the skin, forming a mucous membrane lining for the fistula. If the normal channel is open, nature will close the artificial one. This rule is a fundamental one and must be thoroughly understood. Often a patient enters the hospital with an acute intestinal obstruction. He may be too sick for a radical or curative operation. Drainage and decompression are necessary to save life. If the obstruction is in the small bowel, the Levine duodenal or Miller-Abbott tube is introduced through the nose and attached to a suction apparatus (Wangensteen). This usually obviates the need for enterostomy. If the obstruction is in the large bowel, a vent must be made for the escape of gas and feces. Therefore, a cecostomy or colostomy is performed. If the obstructed bowel is released either spontaneously or through further surgery, we need have no concern over a fecal fistula, it will close of its own accord. If the obstruction remains, the fistula will also remain. Nature always uses the normal channel, except for the exceptions noted, thereby permitting the artificial one to close.

THE USE OF ANTIMICROBIAL AGENTS

In this and preceding chapters we have studied in a limited way the great resources of the body to combat infection. We have discussed the cellular, chemical, and mechanical methods employed by nature locally and systemically in fighting pathogenic microorganisms. Although we have indicated forms of therapy it seems fitting that we here review the present status of the newer drugs in combatting infections, particularly the sulfonamides, penicillin, streptomycin, and aureomycin.

It is well to emphasize again that these agents are adjuvants in the treatment of infections. They cannot and do not take the place of careful

Since there is early severe destruction of tissue in staphylococcus infections, the drugs will not be so valuable. In both types late use of the drugs is useful only to attenuate dissemination.

The drugs hold microorganisms in status quo, while tissue resistance combats them. Therefore, the sulfonamides work best in those tissues which have a high local immunity. Because of a good blood supply, there will be less necrosis and the drugs can reach the area. Local cellular response is greater and is given adequate time to mobilize. The diluting action on toxins of serous fluids, normal serum, or lymph is important. They are not antisulfonamide as is pus.

Pharmacology

The pharmacologic activity of the sulfonamides depends upon solubility, absorption, excretion and acetylation. It is these factors which determine the type drugs to be used. However, toxicity, idiosyncrasies and rate of elimination are also important. The point to remember is that sulfonamides are not specific for specific types of antigens. They are specific in the fact that they are in great local concentration because of one or the other factors mentioned. The acetylated forms of the drugs are therapeutically useless. Sulfadiazine, for example, is the least toxic, is readily absorbed, is rapidly excreted, and is therefore very useful in hemolytic streptococcic, pneumococcic, and staphylococcic infections. Succinylsulfathiazole (sulfasuxidine) and phthalylsulfathiazole (sulfathaladine) are useful in preparing the large intestine for surgery because they cause a lowering of the numbers of coliform bacteria in the bowel. These drugs practically remain in the large intestine (Poth) and have a very low coefficient of absorbability.

Local Use.—Much has been written about the local uses of the drug. Such factors as solubility, absorbability, chemical reaction of the wound, and antisulfonamide factors are all important. One cannot be dogmatic about its use at this time. However, certain factors must be considered. If the action of the drug is bacteriostatic, then its introduction into the infected area has no effect on surface bacteria. It must be absorbed and find its way into the tissues. The only reason then for its local use would be a quick and high local concentration. For this reason it would have to be used in fresh wounds or early in infections when absorption takes place, before antisulfonamide factors are present and before capillaries and lymphatics are blocked. Thus the drug is useless locally in an abscess, a badly macerated wound, or a late infection. Another important factor is the effect of the drugs on tissues. They are not rapidly absorbed and many are irritating. An irritative foreign body is certainly not desirable, especially in serous cavities. Since the drugs are not germicides, they must be sterilized before being used Some have advocated their local use after débridement. If débridement is indicated, infection has not yet occurred and the drug will probably reach the site as quickly and more universally given systemically because antisulfonamide factors have been removed

are present in greater amount than any of the so-called antisulfonamide factors (para-aminobenzoic acid, peptone substances, bacterial extracts, animal tissue and co-enzyme, also vitamin B complex, of which para-aminobenzoic acid is a part, local anesthetic agents of the procaine series), then bacteriostasis will occur. Although many other theories have been used to explain sulfonamide action (peptone theory—Lockwood, 1938, peroxide-catalase theory—Mellon and associates, 1938), the foregoing is perhaps most useful as applied by Stamp, 1939, and Wood, 1940.

Recently still another theory has been advanced. Henry states that other inhibitors of the sulfonamides are certain purines, amino acids, glucose, mercuric chloride, and urethrane. If the theory that metabolites like para-aminobenzoic acid are inhibitors, then some of these substances should not be. He believes that the sulfonamides act on bacteria like narcotics, especially in inhibiting the relatively small amount of total respiration needed for supplying energy in cell division.

Certain changes are observed in the capillaries as a result of treatment with sulfonamides as well as with other drugs such as the iodides (see chapter on glands, thyroid). Perivascular infiltration may cover a wide area around a vessel. Such changes may occur from the use of the sulfonamides, a process not unrelated to periarteritis nodosa. In acute diffuse infections the capillaries are open and permeable. After sulfonamide therapy they soon become blocked with fibrinous plugs. A streptococcic cellulitis becomes converted into a localized lesion, permitting surgical drainage. This is certainly not entirely due to the inhibition of bacterial growth. It may be due in part to an effect on blood lymph capillaries. This is further substantiated by the bizarre types of localization in empyema, peritonitis, cellulitis, and other types of generalized infections. Although there is no proof for these conclusions, clinical observations tend to substantiate them. Probably no one theory explains their actions—perhaps a combination of effects is produced.

Whatever the mode of action, it is apparent that an early large amount of sulfonamide concentration is desirable at the site of infection so that antisulfonamide factors will not have time to form and also so that early capillary occlusion will occur. The drugs are not bacteriocidal; if they were, a continuous supply would have to be available at all times until bacteria were annihilated. They are bacteriostatic for a limited period, allowing the forces of local immunity to combat microorganisms. This immunity is apparently not prevented or delayed by the drugs. The fewer proteolytic substances in a wound, the less competition for the sulfonamides and the better they will behave. It follows that the drug will work best where local reaction is least. Fortunately for the surgeon, then, the type of surgical infection which is helped most is the type in which early surgery is contraindicated. Another way of putting it is: the less damaged the architecture of the part, the more easily will the drug reach it and therefore the more effective it will be. The reverse is also true. Thus early in streptococcus infection the sulfonamides are very useful to invite localization.

individuals although they be mixed together in one compound. In other words, the compounds retain their individual solubility. They are said to have a low risk of renal injury and a negligible incidence of crystalluria, and therefore alkalies and fluids are not as important as in the sulfonamides previously employed alone. There is also a low degree of acetylation. For example, a saturated aqueous solution or urinary solution of sulfadiazine can still be fully saturated with sulfamerazine and still further saturated with sulfamethazine. Furthermore, the effectiveness of the compounds is said to be greater when used in combination than when used singly. The *drugs are put out in the form of a tablet or in a suspension. One brand* of triple sulfonamide mixtures is known as Terfonyl (Squibb). The tablets contain 0.167 Gm. each of sulfadiazine, sulfamerazine, and Sulfamethazine (0.5 Gm. of sulfonamides). The suspension contains 0.167 Gm. each of sulfadiazine, sulfamerazine, and Sulfamethazine per 5 c.c. of suspension (0.5 Gm. of sulfonamides per teaspoonful).

Sulfonamides are also used to reduce the coliform flora of bacteria in the *large intestine. Sulfasuxidine is absorbed very slowly and may* be used as follows for preoperative bowel preparation: 0.25 Gm. per kilogram of body weight divided in four doses per twenty-four hours at six-hour intervals. The tablets are 0.5 Gm. each. Other indications for the drug are ulcerative colitis and regional enteritis. In these diseases it is given in one-half the above dosage. Sulfathaladine (phthalylsulfathiazole) is said to be less toxic than Sulfasuxidine and may be used in smaller doses; for example, as *an adjunct to surgery* it may be given in the dose of 0.1 Gm. per kilogram of body weight. The tablets come in 0.5 Gm. size. In ulcerative colitis and regional enteritis a smaller dose is used—usually about .05 Gm. per kilogram up to 0.1 Gm. per kilogram per day.

Closely related drugs, the sulfones (Diasone, Promin and Promizole), are being used with encouraging results in the treatment of leprosy. Still a newer type of sulfonamide is Thalamyd (Schering) which is phthalylsulfacetimide. This drug is said to have antibacterial action for enteric organisms such as *Escherichia coli, Shigella dysenteriae, Shigella paradysenteriae, Streptococcus faecalis,* and *Vibrio cholerae.* The drug is used in ulcerative colitis and also in the preoperative sterilization of the intestines. The dose is 0.2 Gm. per kilogram of body weight in twenty-four hours. Usually 4 to 6 Gm. per day suffice for adults with ulcerative colitis but larger doses are used before surgery and in acute dysentery.

All drugs which destroy or inhibit the growth of coliform organisms in the large intestine may interfere with the formation of vitamin K_2 and therefore this vitamin is given daily as long as the drugs are employed.

Toxic Effects.—Almost every type of reaction has been observed. The more common ones are:

1. Effects on blood and blood vessels (agranulocytosis, acute hemolytic anemia, aplastic anemia, methemoglobinemia, purpura hemorrhagica, thrombocytopenic purpura)

and the blood supply improved. In potentially infected or infected wounds where drainage is used or the wound is left open, the drugs may be safely employed. However, they are lost in great measure with the exudate. If the local principles of wound healing are adhered to and if infections are treated according to sound surgical principles, there will be no need for the local use of the drugs. If they are violated, the drugs cannot be relied upon to perform the miracles which have been erroneously attributed to them.

Indications and Contraindications.—Throughout the book mention will be made of specific clinical indications. In using the drug there may be a sensitization of the individual which may prevent their future use and bacteria may become immune in such persons, rendering the drug useless. Therefore, these compounds should be used only where definitely indicated.

Names of Drugs.—There are many varieties which are in use. Some are still in the experimental stage. For individual variations the student is referred to a text on pharmacology and therapeutics. The original sulfanilamide is the least irritating and most valuable locally. It is effective though more toxic than other compounds. The others can only be mentioned. They are sulfapyridine, sulfadiazine, sulfaguanidine, phthalylsulfathiazole (Sulfathaladine), succinylsulfathiazole (Sulfasuxidine) sulfamerazine, and Sulfamylon.

Dose and Mode of Administration.—The sulfonamides are usually given by mouth with adequate alkalinization to minimize crystalluria. When oral administration is not possible, soluble salts may be administered intravenously (5 Gm. as an initial dose and then 3 Gm. of a 1 per cent solution three times a day) by rectum or vagina. Absorption takes place from wounds and even the intact skin. Only sterilized powder should be used intravenously in solution. Doses are extremely variable. Sulfanilimide is given to adults in initial doses of 1 Gm. per 9 kilograms (20 pounds) of body weight and repeated in twenty-four hours in six doses. Maintenance dose is 10 Gm. (150 grains) every twenty-four hours until a blood level of 10 to 15 mg. per cent is reached. Another method of oral administration is to give 4 Gm. as an initial dose and then 1.0 to 1.5 Gm. every four hours. In either case equal amounts of sodium bicarbonate should be given and liberal amounts of water consumed. After the temperature has been normal for twenty-four hours the dose may be cut in half. For children up to 12 years a proportionately greater dose may be employed because fluid intake per kilogram is great. Sixty milligrams (1 grain) per pound is a good initial dose. This may be followed by an equal amount every twenty-four hours in divided doses.

Since sulfadiazine is less toxic, it may be used in larger doses and may be given intravenously. Orally 4 to 6 Gm. may be given as an initial dose and then 1.5 Gm. four times a day. Effective blood concentration is 8 to 15 mg. per cent. Parenterally 5 Gm. may be used intravenously and then 3 Gm. of a 1 per cent solution three times a day. Recently sulfonamides have been used in mixtures. The triple sulfonamides are found to act as

which will enable the physician to give a type of penicillin which is rapidly absorbed but which will be excreted rapidly or penicillin which is slowly absorbed.

Sodium penicillin or crystalline sodium penicillin G is a preparation which is extremely soluble and may be dissolved in small amounts of sterile distilled water or sterile isotonic salt solution or 5 per cent dextrose solution. The dose for intravenous injection is 10,000 to 50,000 units per cubic centimeter of sterile isotonic solution of sodium chloride. Usually it is given along with intravenous solutions for the maintenance of water balance; 100,000 to 200,000 units are given with each injection. For constant intravenous drip, 25 to 50 *units per cubic centimeter of sterile saline solution* or 5 per cent glucose solution should be given. For intramuscular injection, 50,000 units per cubic centimeter of isotonic solution of sodium chloride should be given or 100,000 units in 2 c.c. By giving the solution intramuscularly the concentration may be more sustained and the blood levels will remain comparatively high.

Preparations of penicillin are now available which prevent rapid absorption. At first an ice bag was applied to the area of injection to produce vasoconstriction and, therefore, to slow the rate of absorption. At present, there are many preparations available which will accomplish this end without the use of vasoconstricting agents. Crysticillin (Squibb) is a *brand of procaine penicillin G for aqueous injection.* This is absorbed slowly and an initial dose of 300,000 units may be given intramuscularly dissolved in 1.2 c.c. of sterile distilled water or sterile isotonic sodium chloride solution. This will be absorbed over a long period because it has a low water solubility. *Another preparation for delayed action is* Depo-penicillin (Upjohn). There are 300,000 units per cubic centimeter. This is a crystalline procaine penicillin G suspended in peanut oil and containing 2 per cent w/v of aluminum monostearate. This, also, is slowly absorbed. Still another is Duracillin (Lilly) which is a crystalline procaine penicillin G in sesame oil. Penicillin S-R (Parke-Davis) represents a combination of procaine penicillin G with buffered crystalline sodium penicillin G. The rationale for the use of this combination is that the procaine penicillin G will be absorbed slowly whereas the sodium penicillin G will be absorbed very rapidly, the mixture giving an immediate effect and then a prolonged or sustained effect. In the acute pneumococcic, staphylococcic, or streptococcic infections, 400,000 units, that is 1 c.c. of the preparation, may be given daily and continued daily for at least forty-eight hours after the temperature has returned to normal. When indicated in severe infections dosages as high as 800,000 units may be employed twice daily. This, then, represents a combination of penicillin, which is absorbed quickly and which has an absorption that is extremely slow. All of the "fortified" products have the advantage of prolonged action so that continuous intravenous injection of the drug or intramuscular injection every three hours may be avoided. However, it is felt by many observers that *since the rate* of absorbability does vary, that to be safe in severe infection, it is, perhaps,

2. Skin (dermatitis exfoliativa), other types of dermatitis, cyanosis
3. Gastrointestinal (vomiting, nausea, diarrhea)
4. Urinary tract (azotemia due to urinary obstructions from crystalluria or renal insufficiency or sulfonamide mud in Bowman's capsule
5. Liver (hepatitis, toxic necrosis, blue jaundice may be hemolytic or intrahepatic)
6. Central nervous system (dizziness, tinnitis, psychosis, and convulsions
7. Fever

These manifestations may occur from comparatively small doses in sensitive individuals, whereas while most of these reactions are in themselves harmless, they emphasize the importance of using the drugs only where definitely indicated because such reactions occur more commonly in patients having had the drugs. Furthermore, they *contraindicate to a* greater or lesser extent their continued use.

Antibiotics

Penicillin.—Penicillin is derived from a mold, *Penicillium notatum*. Alexander Fleming of St. Mary's Hospital, London, first described it in 1929. It was not until the stress of war casualties became acute that the possibilities of this drug were really explored. This was principally through the efforts of Chain and Florey in 1940.

Action.—The exact way in which penicillin inhibits bacterial growth is not known. However, it appears that the drug does not interrupt the growth of bacteria but prevents cellular division in vitro and in vivo with the frequent production of giant forms. It appears to have an antiendotoxin action also. It is fairly well known, however, that it does not affect animal cells either in their growth or metabolism. It may be said then that its toxicity is extremely low. However, it may have a direct toxic and primary irritant effect, perhaps due to impurities, especially when used intrathecally. It may also have antigenic properties (erythema, hives, angioneurotic edema, dizziness, epistaxis, etc.) or therapeutic shock excitant effects (Jarisch-Herxheimer), producing convulsions. Indirect effects are also listed; namely, too rapid healing of a coronary or liver lesion may have deleterious effects on these organs.

It is effective in all staphylococcic infections with and without bacteriemia, all cases of clostridial infections, all hemolytic streptococcic infections locally and with bacteriemia, all anaerobic streptococcic infections, all pneumococcic infections, all gonococcic and meningococcic infections, and also gram-positive bacilli and spirochetal infections. It is ineffective against gram-negative and acid-fast bacilli.

Dosage and Administration.—Since penicillin is rapidly excreted in the urine (two to four hours), a continuous supply should be available. It may be given orally, by continuous intravenous, or by subcutaneous or intramuscular injection. Various preparations of penicillin are available

thricin concentrate to be diluted to 1,000 c.c. These solutions always contain 0.5 mg. of tyrothricin per cubic centimeter.

Streptothricin.—Streptothricin is a bactericidal substance from a soil Streptothrix *(Actinomyces lavendulae).* It prevents the growth of *Escherichia coli* and other gram-negative bacteria. It also has an antibiotic action against numerous fungi and yeasts. In the experimental animal it is toxic in large doses. Robinson suggests that this product may be useful in the treatment of bacillary dysentery and typhoid and colon infections. It may therefore supplement penicillin which is not effective against gram-negative infection. As yet it is still in the experimental stage.

Streptomycin.—Streptomycin is an antibiotic derived from a strain of *Actinomyces griseus.* It is used clinically as streptomycin hydrochloride and streptomycin sulfate and is particularly useful in the treatment of gram-negative bacilli infections. It may be given intramuscularly, subcutaneously, intrathecally, intrapleurally, and intraperitoneally. Very little is absorbed from the gastrointestinal tract, but it is useful orally in doses of 1 Gm. every six hours to reduce the number of coliform bacteria in the colon. The average dose for intramuscular use is 1 to 2 Gm. daily in divided doses at six-hour intervals for 7-14 days. In children under 2 years of age up to 0.4 Gm. may be given daily. It is frequently given with penicillin and may be mixed in the same syringe, avoiding separate injections. Streptomycin has been most effective in the treatment of tularemia, *Hemophilus influenzae* infections, urinary tract infections due to gram-negative bacilli, bacteriemias and meningitis due to gram-negative infections, and peritonitis due to colon bacillus and in conjunction wth penicillin in all types of peritonitis and tuberculosis. Toxic effects include histamine-like reactions, headache, vertigo, and eighth nerve deafness when given in very large doses, neurological disturbances, paresthesias, hypersensitive reactions, fever, skin eruptions, and eosinophilia. After about two weeks its effectiveness is greatly reduced.

Dihydrostreptomycin.—Dihydrostreptomycin is the dihydro derivative of streptomycin A which is pure streptomycin. Mannosidostreptomycin (streptomycin B) also has a dihydro derivative (dihydromannosidostreptomycin). These antibiotics produced in the laboratory from streptomycin are said to be less toxic and may therefore be given for a longer period of time. Streptomycin and dihydrostreptomycin are used in the treatment of tuberculosis in a daily dosage of 1 Gm. up to forty-two days of treatment; 0.5 Gm. is given intramuscularly every twelve hours. With this dosage there is less likelihood for toxic reactions. Also in the smaller dosage the development of a resistant strain of tubercle bacilli making it impossible to employ streptomycin in the future is not apt to arise. Dosage of more than 1 Gm. may be followed by more toxic reactions involving the eighth nerve without increasing the therapeutic response. Extending the treatment beyond forty-two days results in greater clinical response, but there is the danger of developing a resistant strain of bacteria. The

best to rely upon an injection of the soluble form of penicillin or crystalline sodium penicillin G so that one will be sure of its absorbability. This is given every six hours in the dosage required which is usually 100,000 to 300,000 units as the indications demand. The toxic effects of all of the penicillin products which are fortified, so to speak, and which prevent rapid absorption are not great and many products have very low toxic action. The patients who are allergic to penicillin or to procaine may develop hives or angioneurotic edema. Such patients may be treated effectively by the antihistamine drugs.

Penicillin may be used locally in solution or soluble jellies or as a powder. It has some local irritating effects and although it is not readily absorbed in this way, sensitizations do occur. It is therefore profitable to give it intramuscularly as well as locally should such treatment be indicated.

Here again emphasis should be placed on the fact that the drug is an adjuvant to surgical treatment. For example, we treated a large number of patients with empyema thoraces by thoracentesis and injection of the empyema cavity with sodium penicillin C. This sterilized the cavity readily but, as we have seen, such cavities usually must be drained to permit proper wound healing. We found, therefore, that the cavities filled with purulent exudates over and over again with recurrence of fever. Only after surgical drainage did healing occur. Likewise a gross violation of surgical technique will not be mitigated by penicillin. Perhaps when used early some cures may result from penicillin alone.

Gramicidin and Tyrocidine.—Gramicidin and tyrocidine are produced in cultures of *Bacillus brevis* (a gram-positive aerobic spore-forming soil organism). Tyrothricin consists of both gramicidin and tyrocidine.

Action.—These substances are effective against gram-positive organisms, although gonococci and meningococci are somewhat susceptible. *Gramicidin* is toxic for erythrocytes and spermatozoa also. Its action is said to be due at least in part to inhibition of the bacterial enzymatic action and retardation of growth, causing lysis of susceptible bacteria. *Tyrocidine* is toxic not only for bacteria, but also for all types of living cells. It is therefore like an antiseptic in that it completely and irreversibly inhibits cellular metabolism. Therefore it is not suitable for either local or systemic use.

Dosage and Use.—*Tyrothricin* is used in solutions for *local use only.* Even its introduction in body cavities with adequate drainage is not free from danger. Its chief use thus far has been in indolent superficial ulcers. Tyrothricin concentrate (Sharp & Dohme) is supplied when diluted to make an isotonic solution which contains 0.5 mg. of tyrothricin per cubic centimeter. Three dosage forms are available: one is a 1 c.c. ampule containing a solution of tyrothricin, 25 mg. per cubic centimeter. This is diluted to 50 c.c. of sterile distilled water; the second is a vial containing 10 c.c. of tyrothricin concentrate to be diluted to 500 c.c. with sterile distilled water; the third, for large quantities, is a 20 c.c. ampule of tyro-

fections, bacillary urinary infections, rickettsial diseases, and lymphopathia venereum. The drug is given by mouth in doses of 50 mg. per kilogram of body weight. The dose varies from 3 to 6 Gm. the first day and 2 to 3 Gm. thereafter. Toxic effects are slight. Chloromycetin is obtained in sealed capsules containing 0.25 mg. each.

The great variety of drugs which are now available and which are being developed afford the physician a choice of therapy in so-called "resistant" infections. Thus in penicillin-resistant infection, Chloromycetin may be useful, etc. Also various combinations of drugs are extremely beneficial because few infections are due entirely to one strain of organism.

average daily dose for children is about 7 mg. per pound of body weight; that is, approximately 15 mg. per kilogram of body weight.

Aureomycin.—Aureomycin is an antibiotic derived from a strain of *Streptomyces aureofaciens.* It has been used in rickettsial diseases (Q fever, Rocky Mountain spotted fever, murine typhus, and rickettsial pox) brucellosis, typhoid fever, and urinary infections caused by the coli-aerogenes group and *Streptococcus faecalis.* Aureomycin hydrochloride is given orally (0.25 Gm. capsules in doses of 0.75 to 1 Gm. every six hours. This dosage maintains a constant serum level of 2 to 6 mg. per milliliter. The drug diffuses into most body fluids and tissues, including the cerebrospinal fluid. The use of aureomycin against virus diseases, buboes (Ducrey's bacillus), and streptococcal and staphylococcal infections is also encouraging. Aureomycin may be used in smaller dosage for less virulent infections; 25 mg. per kilogram of body weight every twenty-four hours divided into four equal doses or 500 mg. every six hours for average adults is a desirable way to give the drug. The full dosage should be continued for one to two days after the temperature has returned to normal. Aureomycin hydrochloride may be given parenterally, 1 c.c. for each 10 mg. of aureomycin. The diluent is leucine, 2.6 per cent solution. The dose is approximately one-fifth that of the oral dosage. Intravenous use is more apt to be followed by reactions. Nausea and vomiting are frequent upon oral administration, and after intravenous administration thrombophlebitis may occur.

Bacitracin.—Bacitracin was isolated from *Bacillus subtilis* and is a diffusible polypeptide of low molecular weight. It resembles penicillin in its activity against gram-positive bacteria and spirochetes. Bacitracin is excreted by glomerular filtration, and blood levels are maintained for five to ten hours. The drug is most useful as a topical application for various infections (100 to 200 units per cubic centimeter of physiological saline). It may be given intramuscularly but has little effect orally. Also local injection around boils (500 units per c.c.) using 0.1 to 0.5 c.c. has been advocated. Toxic effects are chiefly on the kidneys; however, this may be due to impurities.

Subtilin, Subtenolin, and Bacillomycin.—These are all derivatives of *Bacillus subtilis* and show promise of being helpful in tuberculosis, typhoid, and fungus infections, respectively.

Polymyxin.—Polymyxin has been isolated from the soil organism *Bacillus polymyxa.* Given intramuscularly in divided doses of 0.2 to 0.5 Gm. daily, usually about 3 mg. per kilogram of body weight, the drug is said to be useful in the treatment of brucellosis, pneumonia, and typhoid fever. It has serious nephrotoxic properties and is therefore still in the experimental stage.

Chloromycetin.—Chloromycetin comes from a species of streptomyces *(venezuelae)* and contains nonionic chlorine. It can be prepared synthetically. It is used in the treatment of typhoid fever, typhus, salmonella in-

Fig. 37—Ulcers. Diagram indicating some of the more important clinical characteristics and their possible significance. The site of the ulcer is also important, as for example; lower lip—syphilis or carcinoma; inner side of lower leg—varicose ulcer; outer side of upper leg—syphilitic ulcer; sole of foot—neuropathic ulcer, etc. Biopsy, smears, and general examination are always indicated to make or confirm the diagnosis.

Chapter 6

ULCER AND GANGRENE—WOUNDS WHICH DO NOT HEAL ACCORDING TO THE NORMAL LAWS OF REPAIR

An ulcer is a sore or a solution of continuity of the surface. It is a defect in which healing does not occur according to the normal laws of repair or in which repair has been delayed. Much can be learned by careful clinical study of the ulcer. (1) The *edge*, if raised, may mean the presence of active infection or new growth; if overhanging, it indicates that some active process, such as syphilis, is destroying the granulations but sparing the skin. (2) The *floor*, if covered with red granulations, indicates that the ulcer is acute; if pale and fibrosed, it indicates that the ulcer is old. (3) If the *surrounding tissue* shows venous stasis, there will be no healing. (4) The *secretions*, if purulent, indicate a pyogenic infection; if serosanguineous, a streptococcic infection or simply a passive congestion, as in varicose ulcer. (5) *Position*. An ulcer on the lower lip indicates squamous-cell or prickle-cell carcinoma; on the cheek, basal-cell carcinoma or rodent ulcer; on the upper outer leg, syphilis. Although in a given disease the position is not invariable, the sites which have been described are characteristic. Thus an ulcer differs from a wound which is healing by second intention in a normal manner. For in the latter, granulation tissue fills the defect and then the skin or mucous membrane grows across it. Diagnosis is made by a careful history, general and local physical examination, and laboratory tests including serology, smears, and biopsy from the ulcer.

Gangrene is the death of a part. The term *gangrene* is usually used to imply the death of a large area, such as an extremity, whereas *necrosis* generally refers to the death of a smaller area of tissue. Some authors use the term gangrene to mean necrosis with invasion of saprophytic organisms—wet gangrene. This type is seen peripherally in some cases and usually when internal viscera are involved. The dry variety is described then as infarction due to vascular causes or as ischemic necrosis.

A classification of ulcers and gangrene may be based on a number of different criteria: (1) clinical manifestations, (2) etiological factors, and (3) pathological changes, according to the disease process that is present.

The following classification is based on etiology:

A. Direct injury to the part
  1. Trauma to tissues (severe crushing force)
  2. Prolonged pressure
     a. Decubitus ulcer
     b. Splints
     c. Volkmann's ischemic contracture
     d. Crush syndrome
  3. Thermal injury
     a. Heat burns and scalds
     b. Electrical burns
     c. Radium and x ray burns

Fig. 37.—Ulcers. Diagram indicating some of the more important clinical characteristics and their possible significance. The site of the ulcer is also important, as for example; lower lip—syphilis or carcinoma; inner side of lower leg—varicose ulcer; outer side of upper leg—syphilitic ulcer; sole of foot—neuropathic ulcer, etc. Biopsy, smears, and general examination are always indicated to make or confirm the diagnosis.

4. Chemical
   a. Strong acids and alkalies
   b. Weak acids (carbolic, lysol, etc.)
   c. Injection of drugs (superficial gangrene)
      (1) Neoarsphenamine
      (2) Adrenalin
      (3) Ergot (local or general)

B. Indirect injury due to circulatory disorders
1. Venous congestion
   a. Varicose veins
2. Arterial causes
   a. Functional
      (1) Vasodilatory—erythromelalgia
      (2) Vasospastic—Raynaud's disease
      (3) Combination—Sudeck's post traumatic dystrophy of the extremities
   b. Organic causes of gangrene
      (1) Arteriosclerosis (senile)
      (2) Diabetes
      (3) Embolism (in acute infections, in sepsis, postoperatively, etc.)
      (4) Thromboangiitis obliterans; Buerger's disease
3. Lymphedema
   Ulcers may occur due to interference with superficial circulation of blood

C. Gangrene of infectious origin
1. Gas gangrene
2. Phlegmon or diffuse cellulitis
3. Hospital gangrene (phagedena or wound diphtheria)
4. Noma (gangrenous stomatitis); Hunner's ulcer of the urinary bladder
5. Ulcers due to specific bacteria or virus
   a. Tuberculosis
   b. Syphilis
   c. Mycotic infections
   d. Chancroid
   e. Lymphogranuloma inguinale
   f. Granuloma inguinale
6. Leprosy

D. Neuropathic ulcers
1. Mal perforant
2. Corneal ulcer (after trigeminal nerve operation)
3. Peptic ulcer (?)

E. Malignant ulcer
1. Basocellular
2. Marjolin's ulcer (old burned area)
3. Spinocellular

F. Ulcers associated with splenomegaly
1. Sickle-cell anemia
2. Splenic neutropenia
3. Banti's syndrome
4. Hemolytic (spherocytic-acholuric) jaundice

G. Disturbances of fat metabolism

1. Local fat necrosis (lipogranuloma) of breast and abdominal wall
2. Lipophage granulomas (Darier sarcoid; erythema induratum, Bazin's disease—may be tuberculids or tuberculosis in fat)
3. Relapsing febrile, nodular, nonsuppurative panniculitis or Weber-Christian's disease—etiology is unknown
4. Necrobiosis lipoidica diabeticorum

H. Combinations

1. Ulcer of tongue in syphilis
2. Leprosy and neuropathic causes

DIRECT INJURY TO THE PART

Trauma to Tissues

Trauma to the tissue caused by severe crushing force needs no examples. It simply devitalizes the tissue so extensively that sloughing occurs and the remaining devitalized tissue is slow to heal.

Fig. 38.—Decubitus ulcer. Case of myelitis.

Prolonged Pressure

Decubitus Ulcer.—Decubitus ulcer (bed sore) is usually seen in old people and in those who are debilitated or have been in bed for a long time. This lesion occurs on the posterior parts of the body that are in constant contact with the bed—the sacrum, the heels, the shoulder blades; also over the trochanters and ilia. By far the most common place is over the sacrum, for here there is direct pressure of skin against bone, which interferes with the blood supply, and moisture (due to soiling or per-

spiration), which causes maceration in a potentially infected area. These sores can be prevented by changing the patient's position frequently and by keeping him clean and dry. Should any signs of redness or blister occur, an ulcer may easily result. This is practically always followed by infection. After an ulcer has formed, the treatment is to relieve pressure (by a rubber ring or by having the patient lie in a prone position) and to keep the part clean and dry. Antiseptics play a minor role; however, there is no objection to the use of mild ones, such as boric acid or one-half per cent Chlorazene. Normal salt solution is probably just as effective. Some use stimulative ointments, such as scarlet red salve; pectin-agar acid mixtures have been used with good results. A far better plan of treatment is to wait for granulation of the ulcer bed and then slide full-thickness adjacent flaps into place after excising the devitalized margins of the ulcer. In paraplegic patients this may be done with excellent results. In others it should be attempted only after improvement of the general condition of the patient. In aged and debilitated patients the closure may be done in stages, or split-thickness grafts may be used.

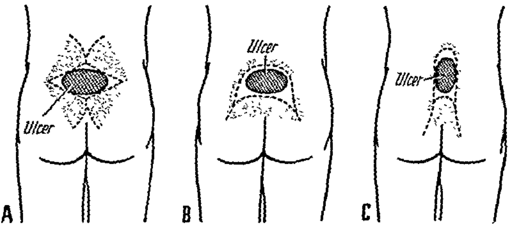

Fig. 39.—Treatment of decubitus ulcers. Formerly the treatment of decubitus ulcers and of pilonidal cysts and sinuses was excision of the diseased tissues and then a long period of waiting until the healthy granulations appeared. After this occurred, skin grafts were applied, usually of the split-thickness free graft type. It is now known that with proper attention to the general condition of the patient and with adequate mobilization of flaps that pilonidal sinuses and decubitus ulcers may be excised and closed primarily. *A*, *B*, and *C* are a few examples of this procedure. Obviously the type of excision will vary, depending upon the position and configuration of the ulcer. In every instance it will be noted that adequate mobilization of flaps must be secured and that suture lines must not be under tension. Then with firm pressure dressings, wounds will heal provided the general condition of the patient has been properly cared for.

Splints.—When splints are applied too tight, there is constant pressure, which devitalizes the skin. Therefore, there should always be a heavy padding around the splints to avoid pressure, especially over bony prominences. Plaster casts carefully applied need very little padding.

Volkmann's Ischemic Contracture.—This is a horrible complication resulting from venous obstruction, with asphyxia of the tissues and their subsequent destruction. This is followed by extensive cicatrization of muscle, tendon, and fascia, with permanent deformity and crippling of the part. It is usually seen after fractures of the elbow that have been

immobilized in acute flexion or in tight casts which interfere with the venous return, although the same process has been described in the foot following fractures in the knee. (See Chapter 21.)

Hemorrhage and edema in the antecubital space may so interfere with venous return as to cause a Volkmann's contracture even though no splints have been used. The increase of hydrostatic pressure in the veins causes a loss of blood plasma, with actual rupture of the veins and hemorrhage. Although the arteries are not occluded, the obstruction causes a rise in venous pressure equal to the systolic pressure in the capillaries and arterioles; all circulation ceases and death of the tissue follows. There is evidence to show that a sufficient collateral venous circulation exists normally in the elbow region. Horwitz believes there is interference with the arterial circulation by direct occlusion. This, of course, may be true in some cases. Usually, however, the radial pulse is normal or only slightly weakened.

If there are pain, swelling, and cyanosis in an extremity, the danger of Volkmann's contracture is imminent. Treatment consists in immediate removal of the cast or splint, extension of the arm, and, in some cases, multiple incisions in the edematous area to relieve pressure. Once necrosis has occurred, the arm and hand will atrophy and the latter will assume a characteristic deformity known as "claw hand." This illustrates the importance of close observation of a fractured extremity.

Wringer injuries are produced by the compression which the rollers exert on the hand, forearm, and arm. This injury is followed by extreme swelling along the entire arm. The pathological effects may be destruction of muscle and tendon due to direct trauma or indirectly due to interference with circulation as in Volkmann's contracture. Children are usually the victims. The treatment should include a pressure bandage applied over liberal wads of mechanics' waste equally distributed; also, elevation of the arm. Repeated injections of physiological saline solution subcutaneously has been used by us with good results. Incisions in the antecubital space may be necessary to relieve pressure, which is especially apt to occlude venous return in this area. The application of cold has been advocated by some.

Needless to say, all electric wringers should be equipped with an automatic cut-off device.

Crush Syndrome.—This will be discussed in Chapter 14 under shock. Severe injuries to the extremities during World War II were common in England, especially in civilians who were crushed under falling buildings. If the legs were severely compressed, the patients exhibited all of the symptoms of shock when compression was removed. By standard treatments such individuals responded for several days only to die with a second group of symptoms resembling uremia and accompanied by anuria. Tourniquets should not be used in such extremities. Local treatment consists of pressure bandage or subcutaneous physiological saline infusions. In addition, plasma and all of the remedies mentioned under burns are indicated.

spiration), which causes maceration in a potentially infected area. These sores can be prevented by changing the patient's position frequently and by keeping him clean and dry. Should any signs of redness or blister occur, an ulcer may easily result. This is practically always followed by infection. After an ulcer has formed, the treatment is to relieve pressure (by a rubber ring or by having the patient lie in a prone position) and to keep the part clean and dry. Antiseptics play a minor role; however, there is no objection to the use of mild ones, such as boric acid or one-half per cent Chlorazene. Normal salt solution is probably just as effective. Some use stimulative ointments, such as scarlet red salve; pectin-agar acid mixtures have been used with good results. A far better plan of treatment is to wait for granulation of the ulcer bed and then slide full-thickness adjacent flaps into place after excising the devitalized margins of the ulcer. In paraplegic patients this may be done with excellent results. In others it should be attempted only after improvement of the general condition of the patient. In aged and debilitated patients the closure may be done in stages, or split-thickness grafts may be used.

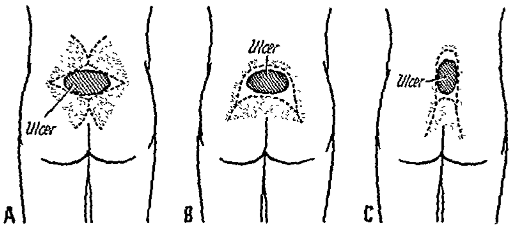

Fig. 39.—Treatment of decubitus ulcers. Formerly the treatment of decubitus ulcers and of pilonidal cysts and sinuses was excision of the diseased tissues and then a long period of waiting until the healthy granulations appeared. After this occurred, skin grafts were applied, usually of the split-thickness free graft type. It is now known that with proper attention to the general condition of the patient and with adequate mobilization of flaps that pilonidal sinuses and decubitus ulcers may be excised and closed primarily. A, B, and C are a few examples of this procedure. Obviously the type of excision will vary, depending upon the position and configuration of the ulcer. In every instance it will be noted that adequate mobilization of flaps must be secured and that suture lines must not be under tension. Then with firm pressure dressings, wounds will heal provided the general condition of the patient has been properly cared for.

Splints.—When splints are applied too tight, there is constant pressure, which devitalizes the skin. Therefore, there should always be a heavy padding around the splints to avoid pressure, especially over bony prominences. Plaster casts carefully applied need very little padding.

Volkmann's Ischemic Contracture.—This is a horrible complication resulting from venous obstruction, with asphyxia of the tissues and their subsequent destruction. This is followed by extensive cicatrization of muscle, tendon, and fascia, with permanent deformity and crippling of the part. It is usually seen after fractures of the elbow that have been

A *third degree* burn destroys the stratum germinativum, becomes infected, and usually requires grafting. But even here the epithelial cells around the hair follicles may minimize scarring.

It is not the depth of the burn that determines the prognosis but the extent of the burn. In other words, the patient may have an entire arm burned off with less serious results than a second degree burn that covers one-half of the body surface, for this may prove fatal. It should be said, however, that a third degree burn involving a similar area would be even worse, not only because of shock, but also due to toxemia, infection, and the difficulty involved in securing autogenous grafts to cover the area. Usually in extensive burns all degrees may be present in different sites simultaneously. It is difficult to ascertain the degree of the burn until the slough occurs.

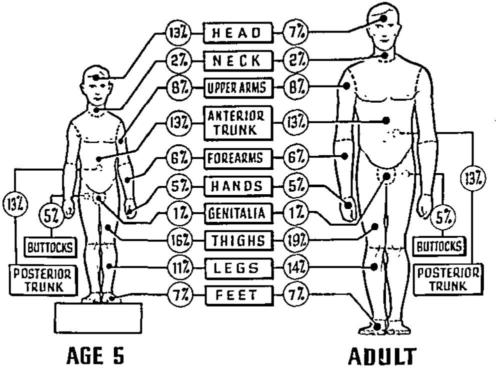

Fig. 41.—Diagram of estimated surface areas of burns. The percentages are based upon figures from Lund and Browder Surg., Gynec. & Obst. 79: 352, 1944.)

The surface area involved is usually calculated according to Berkow's formula: Head, 6 per cent; trunk, 38 per cent (anterior surface, 20 per cent; posterior, 18 per cent); upper extremities, 18 per cent; lower extremities, 38 per cent. For children of all ages trunk and upper extremities are the same but for the head 10 per cent is added for each year the age is below 12 and the same amount is subtracted from the lower extremities.

A very accurate table has been constructed recently by Lund and Browder and is presented herewith (Table III).

It is important to know the surface area involved for accurate recording, prognosis, and treatment.

Thermal Injury

Heat Burns and Scalds.—*Burns* refer to thermal injuries by dry heat; *scalds*, to injuries by moist heat. Chemical and electrical burns will be discussed under separate headings. It is perhaps true that more children die of burns than of diphtreria and scarlet fever together.

Surgical Pathology of Burns.—There are three *degrees* of burns, first, second, and third. The epidermis is composed of four layers: the outer layer is known as the stratum corneum; then come the stratum lucidum, stratum granulosum, and, lastly, the stratum germinativum, or Malpighian layer. This innermost layer is important because it is the one that makes the new cells. Beneath this is the dermis, which is composed of the stratum papillare and the stratum reticulare. Old textbooks described six or seven degrees of burns, depending on how deep they were, the last degree connoting complete destruction of the part, including bone. Such burns are seen in extremities. We now speak of only three kinds in extensive burns because survival does not occur in deeper varieties.

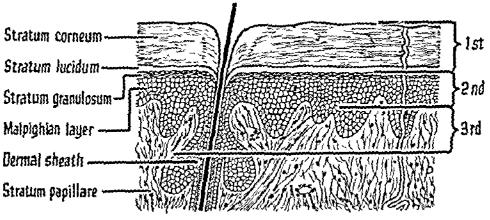

Fig. 40.—Diagram illustrating degrees of burns. The first degree burn involves the *stratum corneum* and may include the *stratum lucidum* and *stratum granulosum*. As a rule, it does not become infected and leaves no scar. The second degree burn involves the *stratum germinativum* (Malpighian layer) in part. There is usually no infection and the skin is mottled, with some areas of scarring. The third degree burn goes deeper, involving the corium (*stratum papillare* and *stratum reticulare*). There is infection and scarring, but even here some islands of epithelium may be seen, arising from the dermal sheath surrounding the hair. A fourth degree burn would involve the *entire skin* and *stratum subcutaneum*. Extensive burns are usually of mixed second and third degree type and require skin grafting to prevent vicious scarring.

A *first degree* burn does not leave a scar. This means that it has not destroyed the stratum germinativum and will not become infected. Since the outer layers (strata corneum, lucidum, and granulosum) of the skin are partially intact, blisters will form in first and second degree burns. It is perhaps the stratum corneum which is most important in retaining fluids which have escaped from peripheral blood vessels.

A *second degree* burn leaves a scar, but not an unsightly one, because it penetrates part of the Malpighian layer but not all of it. The skin will be pitted (pig skin) after healing is complete. Grafting will be unnecessary. A second degree burn usually becomes infected, but this may be averted by proper treatment.

again goes into a state of shock. It is profound and may follow neurogenic shock without an interlude. Beads of perspiration stand out on the patient's forehead, he is cold and clammy, his pulse is rapid, and his respirations are rapid and irregular. Blood pressure falls. This is secondary shock and is due to a loss of blood plasma. Blalock and others produced shock in experimental animals by traumatizing one of the hind-legs. After the death of the animal the traumatized leg was found to be heavier than the normal leg by about 3 per cent of the body weight. This increase in weight was due to a dilation, increased permeability, and rupture of capillaries, which permitted blood plasma and blood to pour into the traumatized tissue, causing hemorrhagic shock. When the leg of the experimental animal was burned instead of pounded, the same increase of weight occurred. In this case the exudate was not whole blood but blood plasma. The result was the same because the blood plasma is the most important part of the blood so far as osmotic pressure is concerned. This explains the high red blood count (6,000,000 or more), the high hemoglobin (16 to 17 Gm.), the low blood protein, and the extremely high hematocrit (almost all cells). The blood was thick and concentrated.

Underhill states that blood becomes thick and sticky, and the blood flow may be almost blocked. The blood has great difficulty in getting through the capillaries and is quickly robbed of its oxygen: the result is a partial asphyxia of the tissues. This in turn causes increased permeability of the capillaries. The hemoglobin content of seriously burned patients may go as high as 209 per cent. A sustained hemoglobin content of 140 per cent is almost invariably fatal. Fibrinogen emboli due to denatured fibrinogen caused by the heat may produce sudden death in burns.

The more extensive the burn, the more blood plasma is lost. This loss sometimes causes death in two to four hours. In addition, with plasma there is loss of sodium, chloride, and plasma proteins (mostly albumin) as well as calcium. There may be an increase in plasma potassium, magnesium, and bilirubin due to tissue and blood cell injury.

As a result of the burn, then, there results an increased permeability of the capillary endothelium, permitting the escape of plasma into the burned areas. The venous blood returning from this zone is concentrated. Although mostly albumin (rather than globulin) is lost, the blood still has a higher osmotic pressure than the intercellular fluid. Consequently this fluid is drawn into the blood stream only to be lost into the injured zone along with more plasma. Soon there is general hemoconcentration with stagnant anoxemia. The osmotic pressure in the blood is greatly reduced, fluid has been depleted from the interstitial spaces, and the blood is viscid. As anoxemia increases, tissue cells are damaged. Capillaries are leaky, and the brain takes oxygen because it is most vulnerable to anoxic states, thereby depriving the intestinal tract, liver, kidney, and muscle from their proper oxygen supply. This, in turn, produces the secondary effects of shock. Dextrose, which is broken down in muscle

CLINICAL COURSE OF A BURN.—

The first stage is the *stage of shock*. The patient develops primary shock which lasts anywhere from two to four hours or longer. Coincidentally, or soon thereafter, secondary shock develops.

The second stage is the *stage of reaction and inflammation*. The patient usually reacts from shock. The burned area becomes fiery red and is extremely painful. There are fever and a rapid pulse. The patient is thirsty.

The third stage is the *stage of toxemia*. It may last for two or three days and may terminate in the death of the patient. The exact cause of the toxemia is unknown. It may be due to absorption from the burned area of toxic "H-substances" liberated by the skin necrosis which occurs, to the infection which inevitably follows, to dehydration, to "water intoxication," or possibly to a combination of causes.

The fourth stage is the *stage of septic toxemia*. Beneath the crusts (of plasma, serum, and cellular debris) which form over the devitalized skin, infection almost invariably occurs. This gives rise to pus formation with septicemia.

The fifth stage is the *stage of granulation*. Just as in any infected wound, healing takes place by second intention after local immunity has been established.

The sixth stage is the stage of *cicatrization*.

Stage of Shock.—We shall discuss the general subject of shock later (Chapter 14). The primary cause of neurogenic shock in a burned patient is pain. However, this type of shock is transitory and lasts only a short time. Then there is generalized vasoconstriction and a transient rise in blood pressure. Within an hour or more after a severe burn the patient

found toxemia from any cause, chemical (cincophen), bacterial (severe sepsis), or absorption of unidentified toxic products, may produce acute duodenal ulcers but not a true peptic ulcer. Dehydration may give rise to thick viscid bile, little mucus, and decreased pancreatic and intestinal juices, setting the stage for intestinal ulceration.

Most deaths from burns occur during the stage of so-called toxemia. There is much controversy concerning the existence of a toxin which circulates in the blood and which produces the devastating changes which are found. These changes may be due to a combination of dehydration, oligoplasmia, anoxemia, anuria, and infection. Some important events occur *in this stage and may be listed as follows:*

1. Destruction of red blood cells with a misleading fall in the hematocrit and possible hemoglobinemia and hemoglobinuria.

2. Focal central necrosis of the liver with a breakdown of liver function. This is said to be more regularly found when the burn has been treated with tannic acid. While it is true that the injection of 5 to 10 per cent tannic acid in rats will produce necrosis of the liver cells in the central portion of the lobule with hemorrhage and leucocytic infiltration, it is equally true that such changes do occur without the use of tannic acid, the latter probably the result of anoxemia and toxemia.

3. Cortical necrosis of the kidneys as well as destruction of convoluted tubules. This may result directly from anoxemia or toxemia or may be the result of hepatic insufficiency, renal insufficiency, or both. *Hepatic incompetency throws the entire work of detoxification on the* kidneys, injuring them. Anuria may result. (See Chapter 23.)

4. Adrenal focal necrosis and hemorrhage leading to adrenal cortical deficiency. Some observers have ascribed the low blood chloride, anhydremia, and low blood pressure to this lesion.

5. Pulmonary congestion and pulmonary edema. The cause of pulmonary congestion may be due to passive or active factors, the former principally through cardiac inadequacy, the result of decreased blood volume and hypostatic effects from immobilization. The latter is a compensatory mechanism which accompanies hyperpnea and an increased demand for oxygen.

Pulmonary edema may be the result of the following sequence of events: As a result of dehydration and hemoconcentration there is a stagnant anoxemia. Hyperpnea results from oxygen lack, increased accumulation of CO_2, and acidosis (q.v.) as well as the increased body temperature. Pulmonary capillaries become more permeable due to dilatation and anoxemia. These factors, together with an increased rate and amplitude of respiration, cause more fluid to leave the capillaries at first by *transudation* and later by *exudation*. Another explanation is based upon the rapid reabsorption of fluid and plasma from the burned area. The loss of fluid plasma from the burned area ceases after local tissues are distended to a pressure equal to capillary pressure. Usually this occurs within the first thirty-six to forty-eight hours. After five to

to carbon dioxide and water, goes only to lactic and pyruvic acid. The liver does not deaminize protein or produce glycogen in adequate amounts. The kidney does not excrete properly. Therefore there is an accumulation of fixed acids and amino acids and a depletion of glycogen with acidosis and azotemia.

The dehydration with loss of intercellular fluid soon leads to a depletion of intracellular fluid as well, with the appearance of increased amounts of potassium and phosphates in the plasma (see Chapters 11 and 12).

There is no vasodepressor substance in the lymph collected from the thoracic duct in burned animals. However, the exclusion of a toxigenic factor as a cause of burn shock has not yet been accomplished.

Stage of Reaction and Inflammation.—After twenty-four to forty-eight hours the patient usually has reacted from shock. A different picture now arises. Instead of a subnormal temperature, there is a rise to 102 to 105°. The tongue is dry, the skin is hot and dry, the blood pressure is up, and the urine is scanty.

The fever and thirst are due to a loss of water and plasma into the burned area and also to an insensible loss of fluid. In addition, no sweating occurs in the burned area or elsewhere in dehydration. (See Chapter 11.) Nitrogenous and other waste products cannot be efficiently eliminated unless there is water available for the formation of urine. When water is constantly lost through the dilated and permeable capillaries there is little available for urine formation. The results are dehydration, acidosis, and azotemia (retention of nonprotein nitrogen, uric acid, and creatinine). Thus the local inflammatory response increases hemoconcentration and dehydration, leading into the stage of toxemia.

Stage of Toxemia.—It is difficult to say how soon after the burn this stage begins. Probably within forty-eight hours and lasting ninety-six hours or more. The patient has absorbed some toxin that has its effect on the body as a whole.

Experimental work on the subject is difficult to interpret. In one experiment two dogs were used and their circulation crossed. One dog was burned; the other was unmolested. The burned animal died; the other recovered. Underhill and co-workers have shown that absorption does not take place from burned areas during the first thirty-six hours. Instead, fluid and plasma are attracted to the burned area. Our experiments show that some absorption begins within ten minutes through the capillaries and lymphatics. There is increased lymph flow during the first six hours. (See Chapter 11.) After thirty-six hours reabsorption takes place over a period of five to six days. In this regard burns react very much like other traumas or infections. The Underhill group felt that early symptoms resulted from dehydration, hemoconcentration, and loss of blood chlorides and serum protein and that the elevation of temperature is probably due to infection. Most experimenters have noted areas of necrosis in the liver. These may account for toxic symptoms.

Rarely the toxemia will cause a duodenal ulcer (Curling's ulcer).

The explanation for this is not entirely clear. Some believe it to be due to inactivation of Brunner's glands. Others believe it is due to toxic or infected bile. Pro

by facilitating reabsorption or by the introduction of fluids and plasma through the gastrointestinal tract or by parenteral means. It is evident that any treatment of extensive burns must take cognizance of the following important integrants: (1) Curtailment of the loss of plasma and electrolytes at the site of the burn no matter how extensive it may be; (2) restoration of lost plasma and electrolytes; (3) facilitation of dilution and excretion of toxins; (4) control of body temperature. If these primary disturbances can be modified, secondary effects such as hemoconcentration, anoxemia, hypochloremia, hepatic and renal insufficiency may be averted to a great extent.

Prevention of Plasma and Fluid Loss Into the Burned Area: This may be accomplished in many ways: (1) The entire burned area may be covered by sterile gauze over which sterile "mechanic's waste" has been placed. Elastic bandages are then wrapped over the area. The external pressure must not be tight enough to prevent venous return but sufficiently snug to increase intercellular tissue space pressure until it is equal to hydrostatic capillary pressure, thus preventing exudation. Indeed this leakage normally ceases if the stratum corneum is intact after the tissues are distended to a pressure equal to the capillary hydrostatic pressure. (2) The use of physiological saline solution into the burned area. This is thought to curtail the loss of plasma and electrolytes and also to make possible the dilution and excretion of hypothetical toxins, to control body temperature, and to prevent pulmonary edema and anuria. (3) A 5 per cent acqueous solution of tannic acid is still used by some with apparently good results. Tannic acid is sprayed on the burned area to form a tough crust. It is said to minimize the leakage of blood plasma and to delimit shock. Tannic acid has also been combined with silver nitrate. These solutions further the formation of a crust and relieve pain. In most cases, however, suppuration occurs under the crust. If it does, the crust must be removed and this is a painful and a traumatizing procedure. In addition, liver necrosis has been found more commonly in patients who have had tannic acid treatment, especially the continuous application as in the bath or jellies. Many other solutions have been advocated such as 1 per cent gentian violet. This is also a good antiseptic and forms a more pliable escar. (4) Saline bath. The patient is placed in a tub of warm water in which salt or boric acid has been dissolved.

The average bath tub holds 56 to 60 gallons of water and is ordinarily filled about two-thirds full. A quart jar of salt, or about two pounds, should be used. *Archimedes' principle:* When an object is wholly or partially immersed in a liquid it is buoyed up by a force equal to the weight of the displaced liquid and the center of pressure is where the center of gravity of the submerged portion would be if it were homogeneous.

Undergarments adherent to the burned area are removed. The patient is then left in the tub of isotonic saline solution two to four hours at a time, or continuously.

seven days if no infection ensues absorption is practically complete. It is possible, therefore, that after the third day there may be an excessive blood volume with a decreased urinary output resulting in pulmonary edema. Lastly, the lungs may fill with fluid if there has been too much intravenous therapy without regard to osmotic pressures.

6. The gastrointestinal tract has been mentioned previously as the site of ulcers (Curling's). These may be found in the duodenum and stomach.

Ordinarily dehydration alone may be surmised clinically by the brick-red skin which is loose due to loss of subcutaneous fluid. The mouth and tongue are dry and there is fever. Hemoconcentration gives rise to cyanosis due to stagnant anoxemia with an increased amount of reduced hemoglobin in the circulating blood. This state may lead to generalized edema, including the lungs because of the loss of plasma and the proteins. In burn toxemia any combination may be present making clinical signs unreliable.

Stage of Infection.—Theoretically infection should be prevented. It does not occur in first degree burns and can often be prevented in second degree but not in third degree burns. The skin assumes a dark color and sloughs away; the temperature takes a slightly elevated course. On about the fifth day after the burn crusts form over the devitalized and ulcerated areas. Beneath these crusts bacteria find an excellent medium for development. They multiply rapidly and produce an extensive infection. Then the temperature becomes septic in type.

Stage of Granulation.—If the crusts are removed, thick pus is encountered lying on granulation tissue, just as in any other wound that heals by second intention.

Stage of Cicatrization.—If the burn is of the third degree, the entire area will fill in with granulation tissue. The skin cannot cover the denuded portion because it is too extensive, consequently scar tissue helps fill in the area. Thus a vicious cicatrix may form.

TREATMENT OF BURNS.—There is no unified opinion concerning the management of extensive burns. Much has been written concerning the local treatment of the burned area as well as the general management of shock toxemia, infection, and the secondary results of these states. At the onset we may say that the various claims for local agents must be viewed in the light of the degree of the burn. If it is a first or second degree burn almost any agent will secure a healed uninfected wound. However, in third degree burns the size of the area is very apt to prevent healing by first intention and infection is difficult to avoid. It must be apparent then that the first consideration in the treatment of a burn is to prevent death from the greatest hazard; namely, shock.

Treatment of Burn Shock.—This treatment is based upon two important factors. First, every effort should be made to prevent the loss of plasma and electrolytes, and, second, such loss must be replaced either

available to prevent azotemia (best way to check this is to anchor a catheter and record hourly output), (d) pulse, (e) blood pressure, (f) respiration, (g) color of the skin, (h) dryness of mouth, (i) condition of lungs, especially edema. When in doubt the use of hypodermoclysis with physiological saline is safe.

Rhoads, Wolf, and Lee (quoted by Harkins) use Berkow's formula for estimating the per cent of body surface burned and give 50 c.c. for every per cent, giving one-third the first two hours, one-third the next four hours, and one-third the next six hours.

Harkins' rule: Give 100 c.c. of plasma for every point hematocrit exceeds 45. For children this should be reduced according to body weight. If plasma proteins are below 6 Gm., an additional 25 per cent should be added for each gram below 6.

Cope and Moore believe that fluid must be given to replace that which is lost through wound edema, from the wound surface, by the urine, and by insensible water loss. Their formula is used the first forty-eight hours which are the hours during which most fluid is lost. For wound edema they give a volume equal to 10 per cent of the body weight; for external loss, an amount varying according to the area of the wound surface: burns of 25 to 35 per cent, 1,000 c.c.; 35 to 60 per cent, 2,000 c.c.; 60 per cent and over, 3,000 c.c. Wound edema loss and external loss are added, and two-thirds of this combined volume is given as plasma and one-third as noncolloid isotonic electrolyte solution. The forty-eight hour period is divided into four parts: two parts are scheduled for the first twelve hours, one part for the second twelve hours, and the fourth part for the second twenty-four hour period. Calculations are made from time of burn. The reason for this is that the redistribution of fluid occurs most rapidly in the initial hours of the injury. For renal excretion, 1,500 c.c. of noncolloid fluid are allowed for each twenty-four hours, one-half to be given as isotonic electrolyte intravenously, the other half as glucose in water if given intravenously or as palatable fluids if given by mouth. For the insensible loss, 1,500 c.c. are given for each twenty-four hours or 3,000 c.c. for forty-eight hours of noncolloid electrolyte solution, glucose in water if given intravenously or palatable low salt fluids if given by mouth. A catheter is anchored and hourly outputs charted. Normal is 50 to 200 c.c. per hour. A falling or low hourly output (that is, 30 to 5 c.c. per hour) for three hours or more calls for immediate increase of fluid. Outputs of 200 c.c. per hour for more than six hours signify overtreatment if encountered in the first forty-eight hours or spontaneous diuresis if after the forty-eighth hour, and this amount calls for a cut in the amount of fluid given. The unreliability of this method, however, is evident when we come into the very low urinary output class because it is difficult sometimes to tell whether the therapy is inadequate or whether a renal lesion is present due to anoxemia, dehydration, hemoglobinuria, or damage antedating the burn which renders more output

In 1932 my colleagues and I experimented on guinea pigs. We burned them under sodium amytal anesthesia, then put some of them in various solutions: water, distilled water, normal saline, hypertonic salt solution, and tannic acid solution. The only guinea pigs that died were those that were not soaked. In this group, blood plasma was found on the pads placed in the little pans.

Badly burned patients do not perspire, either in the burned area or in the normal skin. This may be due to the collection of plasma in the intercellular spaces, drawing water out of gland cells, or to dehydration. Some believe it to be due to a sympathetic nervous system imbalance caused by the toxemia. Whatever be the cause, the heat-regulating mechanism is greatly impeded in its action (vaporization through sweating is the most effective means of controlling body temperature). A water bath has the additional advantage of helping to maintain an even body temperature and may prevent heat stroke from occurring during the toxemic stage.

Isotonic saline is about the best solution that can be used. It is not antiseptic and therefore some use 3 per cent boric acid solution. There is no difference in the results. Equipment to keep patients in tubs with thermostatic arrangement for an even temperature is desirable in the treatment of burns. The water should be 75° F. or about 24° C. Patients do not mind being in a tub of water; in fact, they like it. The patient should be left in the tub four or five days, until the stage of toxemia is over.

Patients in the toxemic stage frequently have an inordinately high fever. Since *there is dehydration, body water is not available for sweating, which would lower the* fever by evaporation. The control of the fever is a difficult problem. Some have suggested colon irrigations with cool water. This may result in shock or severe diarrhea. The bath treatment controls the fever fairly well.

There are apparatuses to lift the patient in and out of the water, so that the emunctories may act.

The Restoration of Fluids: If the patient can take fluids by mouth, this is the preferable way to administer them. In most instances of extensive burns this is not possible. Whole blood is needed to carry oxygen and to replace the cells which may be destroyed or lost. Parenteral restoration of fluids is especially indicated in addition to local arrest when the outer skin layers are destroyed, permitting generalized weeping. Plasma is most necessary because it is lost in greatest amounts. The quantity of plasma required may be enormous. Various "rules" have been used to determine the amount of plasma which should be given. No rule is infallible, and since it is the amount of circulating plasma which is important, a quick method of determining the circulating blood volume would be desirable. Even with this information it is the compensatory mechanisms which prevent or permit shock to occur (see Chapter 11). Therefore, at the outset we should say that it is the general condition of the patient which is the best guide. The factors to observe are (a) mental state (conscious or stuporous), (b) temperature—if normal, or nearly so, fluid is present for body temperature control by evaporation, (c) urinary output—if sufficient amounts of urine are excreted, enough water is

provide osmotic pressure but are also inert and therefore on theoretical grounds could not replace the labile active proteins. Their use is still in the experimental stage.

Noncolloid solutions such as physiological saline solution with or without glucose and distilled water with 5 per cent glucose are needed but must be given with sufficient plasma to provide for proper osmotic pressure relations.

If physiological saline solution is injected into the vein of a burned patient, it will leak out into the wound, because the capillaries are extremely permeable. This, in turn, will carry more blood plasma into the burned area, thereby increasing shock. Due to the great loss of blood volume, all arterioles constrict in order to keep up the blood pressure and by so doing force more fluid into the capillaries. Since the hydrostatic pressure in the capillaries is thereby increased and the osmotic pressure is diminished, the salt solution will leak not only into the injured area, but also into intercellular tissues all over the body. The result may be pulmonary and cerebral edema (water intoxication). The same thing may happen if too much water is given by mouth without salt. Blood transfusion is the treatment of choice. Recent evidence indicates that citrated blood plasma, alternated with whole blood, is good treatment to relieve the great hemoconcentration that exists. Blood plasma has a strong osmotic pull. This may not only prevent leakage, but also may attract body fluids into the thickened blood and permit a liberal intake of water by mouth.

The use of isotonic saline solution by hypodermoclysis is safe and for osmotic reasons will not be absorbed unless needed by the blood or unless instilled into tissue spaces under pressure higher than capillary blood pressure or 30 mm. of mercury.

Local Treatment.—The best treatment for small burns is the application of a sterile dressing with pressure as previously described. Blisters should not be opened. The bleb fluid has a protein content of 4.0 Gm. per 100 c.c. Albumin is in greater proportion to globulin than is present in the blood. Fibrinogen, prothrombin, and the diffusible portions of the electrolytes, carbohydrate, and nonprotein nitrogenous substances have the same concentration as that of the blood. Blister fluid rarely coagulates. This is thought to be due to the absence of thrombokinase. This lack of coagulation is important because water-soluble substances placed on the surface of a ruptured bleb will be absorbed. Conversely substances wihch permeate the capillary wall will be found in the bleb (Cope). The fluid in the bleb is usually free from virulent organisms. If the stratum corneum is intact even though killed by heat, it too forms a barrier against infection. Therefore, blisters should be allowed to remain intact and scrubbing of the wound should not be done, the latter because it is also traumatizing and adds to the shock. Later, after six days, as in the treatment of other wounds, q v., local attention to the wound may be given according to sound surgical principles.

impossible and moreover in which it would be dangerous to increase the fluid intake. To test this, a "water tolerance" test is used. One thousand cubic centimeters of fluid are given by vein in forty to sixty minutes, and if an increase in renal output occurs, the kidneys are not at fault and the therapy is inadequate. However, if no renal response occurs, then the kidneys are thought to be at fault and more fluid should not be administered.

Realizing that the hematocrit and protein determination may be normal yet the circulating volume greatly reduced (Chap. 11), we formerly used the following rule in conjunction with careful clinical observation q.v.: Since there are 23 c.c. of plasma for every pound of body weight, the total amount of plasma should be about 23 × body weight. Approximately 55 per cent of the blood is plasma and 45 per cent is cells. If the hematocrit goes up, then, to this degree, plasma may be said to be lost. Therefore, $\frac{\text{\% rise in hematocrit} \times (\text{body weight} \times 23)}{55}$ should roughly indicate the amount of plasma lost. For example, if the hematocrit is 55 and the burned patient's weight 100 pounds, then $\frac{10}{55} \times 2300 = 418$ c.c. of plasma needed as an initial amount. However, the frequent shifts of fluids make replacement by such rules impractical.

Other fluids: If the patient is able to take fluids by mouth they should be given provided an adequate amount of sodium chloride is allowed. It is the sodium which must be replaced (see Chapter 12), although some chloride is needed also. The excess chloride may be eliminated by the kidneys. Recently Fox has advocated the use of sodium lactate orally. There seems to be no proved advantage of this solution over sodium chloride. In all instances the oral administration of fluid should be correlated with careful estimation of plasma proteins and the clinical signs enumerated. A high protein concentrate like Amigen may be given by mouth to supply sufficient protein. However, in the emergency plasma proteins as such are also necessary and should be given as plasma by vein as needed.

Besides whole blood and plasma, other solutions may be used to provide fluid and osmotic pressure requirements. Albumin concentrate was used in conjunction with whole blood by some Army units. It, of course, does not provide globulin but is an excellent substitute for plasma. Solutions of amino acids are also employed by some. Since the liver is unable to deaminize the blood, there is already an excess of these products which depend upon the liver at least in part for their synthesis into usable proteins; therefore they have no place in the treatment of burns unless they may be given by mouth so that the selective absorption of the intestinal canal may assume its normal role. Nonbiologic colloids such as acacia, gelatin, and pectin have also been tried. Acacia is retained in the cells for years and may injure them. Gelatin and pectin

enough healthy skin to use. Grafts take due to the activity of the prickle cell layer of cells which move by pseudopodal prolongation. The stratum germinativum is perhaps even more important in this process. Nourishment is provided for the grafted tissue within about twenty-two to twenty-four hours by the capillary loops in the granulation tissue. The pressure dressings are not disturbed for eight days; then they are carefully removed. Then the area is exposed to the air for one to two hours and fresh dry dressings reapplied.

Burns of the hands constitute a special problem. The saline bath is perhaps best for such injuries. Early grafting of skin with pedicle grafts (as a rule) are necessary to prevent contractures. The hand is then placed in suitable splints.

Summary.—

1. Treat for shock
   a. Prevent loss of plasma
   b. Administer fluids, plasma, and blood as needed
2. Care for local areas after wound immunity has been established.
3. Use skin grafts as needed

Electrical Burns.—Electrical burns are deep and reactionless. Their danger is the electric shock, which may produce a paralysis of the respiratory or cardiac centers. The burn may not be noticeable for several days; then a large slough occurs. There is no special treatment.

Radium and X-Ray Burns.—These are extremely slow to heal. Sometimes they never heal, undergoing carcinomatous or sarcomatous change. All such ulcers should be widely excised. The denuded area may then be covered by mobilization of flaps or skin grafts.

Cold (Frostbite).—Frostbites are very much like burns in that they have a first and a second degree of severity. They are unlike them in one way that must be kept in mind. The blood vessels about the frostbitten area are constricted, causing the skin to turn white before destruction occurs. In addition to frostbite, there is, therefore, a lack of proper blood supply, with venous stasis and consequent thrombosis. The latter has been prevented experimentally by the use of heparin. This is more serious as far as local skin destruction is concerned than in burns, for in frostbites the area is anesthetized, permitting a longer action of cold. Davis studied the hands of aviators who had sustained high altitude frostbite. He describes a wet and dry type. The former occurs because blood enters the capillary bed where plasma is lost through dilated capillary loops. Dry gangrene results from acute peripheral vasoconstriction. Here the arterioles are full of blood and the capillaries are empty. The principal damage is to the endothelium of terminal capillary loops. Mild degrees of frostbite cause an increased permeability of capillaries. Severe injuries from cold are followed by thrombus formation at the arteriole-capillary junction. No thrombi are present in the

Over one hundred different substances have been used in the local treatment of wounds. These vary from simple oil to complex ointments, from isotonic saline bath to soaks in chemical mixtures and antiseptics. Recently sulfonamides which are absorbed (q.v.) and also penicillin jellies have been used. Lastly, such substances as casein, chemotherapeutic membranes and red blood cell pastes have been tried.

It is perhaps correct to assume that any nonirritating substance may be used and that it is rather the rest and infrequent dressings which contribute more to the wound healing than the particular substance employed.

In England the Bunyan envelopes are popular in the treatment of burns. They are made of oiled silk and are of different shapes. There is an inlet and outlet vent permitting thorough irrigation with different fluids. This is similar to our water bath treatment. Even after ulceration has occurred, the patient who has been in a tub of water may be left there if equipment permits; if not, he should thereafter be placed in the bath two or three times a day, for one or two hours, and allowed to rest between times in bed in a heat cradle, so that the sheets will not irritate the wounds. One-fourth per cent Chlorazene solution on the burned area prevents tough crusts from forming and decreases suppuration.

Adjuvants to Treatment.—Oxygen should be given routinely in extensive burns. This may be administered by tent, B.L.B. masks (if the face is not burned, or in an oxygen room. Morphine is necessary to control pain and should be used liberally. The sulfonamides may be given orally, rectally, or intravenously. They will find their way into the burned area readily. This is preferable perhaps to their local use where they may produce local irritation. However, ointments with sulfonamides have been extensively used. Penicillin is superior and should be given intramuscularly in 100,000 unit doses every four hours. The size of the wound in larger burns prevents healing by first intention. Infection creeps in. These drugs help until local immunity occurs. After local immmunity has been established (six to nine days), crusts may be removed. Blisters or blebs which have not ruptured spontaneously may be opened and loose, devitalized skin trimmed. If granulation tissue is healthy, free grafts (Thiersch, split-thickness, or Wolff) may be applied. Unhealthy granulations may be improved by the use of ultraviolet light. Edematous granulation tissue is best treated by pressure bandage with intermittent exposure to the air in a heat cradle (temperature 75° F.). It is absolutely necessary to use skin grafts in third degree burns to prevent viscious cicatrices from forming. If granulation tissue is old and fibrous, it should be excised and then grafted. A viscious scar must also be removed and the raw area covered by free or pedicled grafts (see Chapter 3). Autogenous grafts are used (homogenous, isogenous, and heterogenous grafts are not successful but the two former are sometimes used for the temporary covering they afford). It is often difficult to find

sures are intended to relieve vasoconstriction. They will succeed, of course, only where organic changes have not occurred but they may delimit damage to tissue.

A *chilblain* is a dilated and overdistended vein, with a small thrombus as a rule. Chilblains are painful and tend to recur upon exposure to cold. Warm wool covering for the feet prevents their formation and recurrence.

Immersion Foot.—Immersion foot is a term applied to a condition which results from long immersion of the feet (or, rarely, the hands) in cold water. In World War I the term "trench foot" was used for a similar condition. Men in life rafts or boats whose feet have been immersed in water for long periods are usually the victims. Contributory factors that influence its occurrence and severity according to Ungley are time of exposure, temperature of water (cold is worse, for there is thrombosis and gangrene), footwear (protects for a while but soon constricts due to swelling of feet interfering with circulation), immobility (moving about reduces liability to injury), body cooling, total immersion, repeated soakings or inadequate clothing reducing peripherocirculation, seasickness and starvation, age (men over 40 and under 17 are most susceptible).

There is a prehyperemic stage (one to four days). Extremities are cold, swollen, discolored, and numb with "glove or sock" anesthesia. Pulsations in the dorsalis pedis and posterior tibial arteries may be absent temporarily or permanently when gangrene occurs. The hyperemic stage which follows is characterized by swelling, especially if extremities have been warmed, sensory and motor disturbances, absence of sweating, blisters, ulcers, and gangrene. The posthyperemic stage (weeks to months) brings fresh blisters or infections and cold sensitivity. Treatment consists first of prophylaxis. Shoes and boots should be removed if wet, and grease applied to the feet. Care of the condition resembles that of frostbite, although the lesion occurs in warm waters. There should be no trauma (no massage or walking); warming of the feet must be gradual and slow

Chemical Injury

Acids.—Strong mineral acids (nitric and sulfuric), alkalies (lye), and weak organic acids (carbolic, Lysol, etc.) may cause ulcers on the skin or in the mouth or esophagus, through accident or suicidal intent. Such accidents are not uncommon in children. Of course, the bottles or cans are labeled "poison" but tots who cannot read get hold of them. They should be kept where children cannot reach them. An antidote for carbolic acid on the surface is alcohol. Iodine will produce a superficial burn. Even hydrogen peroxide continuously applied will cause necrosis. It is well to remember that if antidotes are not available, water is extremely useful. It washes irritants from the outside and dilutes them if taken by mouth.

capillaries in such cases. However, if vasoconstriction is released, blisters form and the stratum germinativum is lifted up. This is different from a first degree burn and indicates that cold penetrates deeper. Blisters, then, may mean a return of circulation at least temporarily. It may take six to ten months for the capillary bed to return to normal.

The intima of adjoining arteries is thickened as in endarteritis obliterans proximal to the arterioles. No thrombi are present here. Such *changes occur after* prolonged vasoconstriction.

A significant concomitant cause of the skin destruction is the fact that blood will not part with its oxygen when the skin is sufficiently cold (50° F. or 10° C.). (Lewis.)

Fig. 42.—Gangrene of both feet due to freezing. Boy aged 15 years. Healthy granulations are present. The gangrenous toes have been trimmed away. By this method of conservative care a maximum amount of surface tissue is saved. The granulations were grafted with split-thickness grafts.

Treatment of frostbite will depend on the degree of involvement and the severity of the injury. If extensive, a shocklike syndrome occurs, demanding treatment as discussed under burns. Heparin may be used to delimit the formation of propagating thrombi. Locally the method of choice is a gradual *increase in temperature*. The frostbitten part should be immersed in cold water first and then gradually the temperature may be raised. Warm water should not be used. It causes intense reaction, pain, and local sloughing. Also it is inadvisable to rub ice or snow on the part—*this traumatizes the already devitalized tissue.*

Control of atmospheric temperature is excellent if suitable equipment is available. A beginning environment of 20° C. which is slowly increased is desirable. Other methods are: applying heat to the body as a whole with generalized vasodilation, the action of drugs (amylnitrite, nitroglycerin, alcohol papaverine), drugs which act on the autonomic nervous system (nicotinic acid, mecholin), injection of sympathetic nerve trunks with procaine hydrochloride, and sympathectomy; all such mea-

The cause is an overactive sympathetic nervous system. Pulsations of the arteries remain. There is an increasing tendency to regard Raynaud's disease not as a clinical entity but rather as the peripheral manifestation of some more fundamental disorder, because achalasia of the

Fig. 43.—Raynaud's disease with scleroderma (symmetrical gangrene). Woman 38 years old. Middle finger of right hand has been amputated. Note the tapering fingers, which were moist, cold, and usually cyanotic. The skin is stretched tightly over the joints (sclerodactylia). Improvement followed intermittent arterial occlusion by cuff.

After a short period of time the disease progressed and cervical sympathetic ganglionectomy was done on both sides with great improvement. When last seen, no new areas of gangrene had resulted, although the patient reported that her skin was still stretched tightly over the fingers.

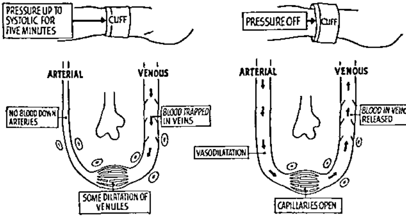

Fig. 44.—Diagram illustrating the effect of arterial occlusion in vasospasm. Pressure causes temporary paralysis of the vasoconstrictors, allowing vasodilatation when the cuff is released.

esophagus is not infrequently a complication; also idiopathic inflammatory reactions in skeletal muscle and the intestinal tract (regional enteritis may be part of this syndrome). The term acrosclerosis is applied to scleroderma and Raynaud's disease (see Chapter 20). Its symptoms have long been regarded as an example of how psychosomatic states

Injection of Drugs.—If more than 1 c.c. of Adrenalin is injected into a single small area, necrosis of tissue may result. This is due to interference with the circulation through arteriolar constriction. Ergot sometimes produces gangrene through its vascular effects. Neoarsphenamine will produce a slough if injected outside the vein.

Indirect Injuries Due to Circulatory Disorders

This group of pathological changes in peripheral vessels is known as peripheral vascular disease and forms an important part of hospital clinical work and private practice.

Venous Congestion

Varicose Veins.—Varicose veins are discussed under the heading of "Veins" in Chapter 17.

Arterial Causes

Functional.—

This may be *vasodilatory* as in Weir Mitchell's erythromlalgia but does not produce necrosis or gangrene. It is often associated with organic diseases of the blood vessels.

In *Raynaud's disease,* usually seen in women, a continual constriction of the vessels produces gangrene of the fingers or toes. This is also known as symmetrical gangrene because it affects both extremities simultaneously. The fingers turn white when cold and red when warm; then they became blue, due to stasis in the venules. They are cold and painful. A related though milder condition is *acrocyanosis* usually seen in young neurotic women. In its most severe form, erythrocyanosis frigida, small round ulcers may appear on the lower legs. Usually, however, the hands and feet are cold and moist with varying degree of cyanosis. Eczematous lesions may be present. Acrodynia (painful extremities) is seen chiefly in infants 9 to 18 months of age. The fingers and toes become swollen and erythematous with a pinkish color. Vasomotor phenomena are present and the child is emotionally disturbed.

Livedo reticularis also causes cyanosis in the extremities, chiefly the lower. It has been called livedo racemosa, livedo annularis, and asphyxia reticularis. The etiology, like Raynaud's disease, is probably primarily an organic or functional spasm of the arterioles with dilation of the capillaries and venules. This gives rise to patchy constant areas of cyanosis on the legs and feet. There is coldness, numbness, and dull aching sensations in the feet.

Rarely a disease known as scleroderma is seen associated with Raynaud's disease. The skin is stretched tightly over the finger joints (sclerodactylia) and appears smooth and glossy. Such patients are said to be "hidebound." Scleroderma may be associated with cardiospasm and stenosis at the cardiac end of the stomach due to fibrosis (achalasia). Fibrosis of the lung may occur also. Is regional ileitis related too? Ergot may produce gangrene due to prolonged constriction of the vessels.

beginning as purely functional disorders may result in severe organic disease. The vascular changes in Raynaud's syndrome are not necessarily due to active vasoconstriction but may result from vasodilatation in the palmar arch with a diversion of blood from the fingers and passive collapse of these vessels. The underlying disease may be organic, vascular, severe secondary anemia, or syphilis.

Treatment must first include a careful search for underlying causes as previously mentioned and the care of such disorders. In addition, measures should be instituted for the relief of vasospasm. These include the application of constriction in the upper arm and leg. It is well to use a sphygmomanometer cuff, inflating it up to systolic pressure (about 130 mm. of mercury) and leaving it on for fifteen to twenty minutes at a time. This is said to produce temporary vasoparesis due to inhibition of vasoconstrictors with vasodilation. In severe cases cervical or lumbar sympathetic ganglionectomy must be done. (See Chapter 18.) Results, however, have not been uniformly good. There is temporary improvement following operations of sympathetic denervation. Hands become warm, pink, and dry. All discomfort leaves, but there often is a recurrence. This may happen in a month to a year. It may be due to the action of adrenalin on the denervated vessels but is more probably the result of reinervation from a peripheral nerve or associated ganglia.

Cervical sympathectomy may be performed as follows: An incision is made from the seventh cervical vertebra downward along the border of the scapula. The trapezius muscle is split, the rhomboids are retracted, and the lumbodorsal fascia is cut transversely. The third rib for

---

cause residual vasospasm is less apt to occur. He therefore divides the sympathetic trunk below the fourth ganglion, encases the decentralized second and third ganglia in a silk cylinder, and sutures the distal end into the muscle (curved arrow in diagram shows division and displacement below the third ganglion). An incision is made medial to the border of the scapula extending from the second to the fifth thoracic spinous processes. The lumbodorsal fascia is divided. The trapezius is divided longitudinally and the rhomboid obliquely, and the longissimus dorsi (longissimus cervicis division) is divided as shown or split longitudinally, as is also the iliocostalis cervicis muscle. A section of the third rib is removed and the transverse process is rongeured away. The pleura is then separated from the vertebral column to the midline and also from the rib for a short distance beyond the line of resection. The second rib is then treated in a similar manner and the intercostal muscles are divided transversely with care so that the intercostal vessels and nerve are not injured. If the chain is severed below the fourth ganglion, then the fourth rib is resected instead of the second. The third intercostal nerve is picked up and divided laterally and then followed medially to the intervertebral foramen, dividing the communicating rami from the anterior, then posterior branch of the intercostal nerve. The posterior branch is divided and then the anterior branch is followed to the arachnoid and divided. Spinal fluid may leak out but is controlled by placing a small piece of Gelfoam over the leak. The first, second, and fourth nerves may be dealt with similarly and the sympathetic ganglia removed or treated according to the Smithwick technique.

B. The entire lower extremity may be denervated of its sympathetic control by removing the first, second, third, and fourth lumbar ganglion. If the first lumbar ganglia are removed bilaterally, loss of ejaculation is apt to occur. This is less likely if the second ganglia are removed The first lumbar ganglion lies inferior to the renal vessels under a layer of fascia in the costovertebral angle. The third ganglion usually lies just above the common iliac artery. We usually employ a retroperitoneal approach because it can be done bilaterally. The slightly oblique incision is made above the level of the umbilicus The external oblique is divided to the edge of the rectus. In obese individuals the rectus muscle may also be divided. The internal oblique and transversalis muscles are divided in the direction of their fibers and the peritoneum is gently reflected from the quadratus and psoas muscles. The genitofemoral nerve is an important landmark, for it lies lateral to the sympathetic chain. The rami are divided and the sympathetic chain removed In obese people in whom it is necessary to remove the first lumbar ganglion, a posterolateral incision very much like that used for nephrectomy is useful.

(Modified from deTakats, G., Surg., Gynec., & Obst. 79: 359, 1944.)

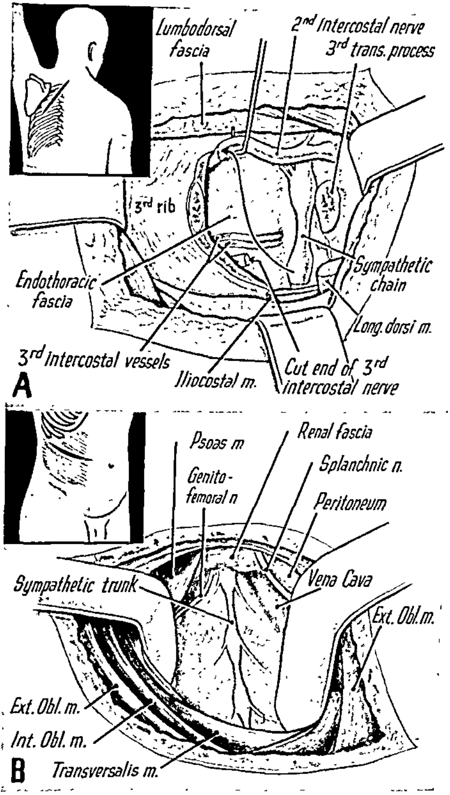

Fig. 45.—A. Sympathectomy of the upper extremity may be accomplished by removing the inferior cervical and first, second, and third thoracic ganglia. Since many synapses are present in these ganglia, the procedure is largely postganglionic in type. Residual vasospasm due to sensitization of smooth muscle to adrenalinlike substances does occur in some cases. Smithwick recommends that the synapses be preserved be-

If the first lumbar ganglia are removed bilaterally, loss of ejaculation is apt to occur. This is less likely if the second ganglia are removed. The first lumbar ganglion lies inferior to the renal vessels under a layer of fascia in the costovertebral angle. The third ganglion usually lies just above the common iliac artery. We usually employ a retroperitoneal approach because it can be done bilaterally. The slightly oblique incision is made above the level of the umbilicus. The external oblique is divided to the edge of the rectus. In obese individuals the rectus muscle may also be divided. The internal oblique and transversalis muscles are divided in the direction of their fibers and the peritoneum is gently reflected from the quadratus and psoas muscles. The genitofemoral nerve is an important landmark, for it lies lateral to the sympathetic chain. The rami are divided and the sympathetic chain removed. In obese people in whom it is necessary to remove the first lumbar ganglion, a posterolateral incision very much like that used for nephrectomy is useful.

(Modified from deTakats, G.: Surg., Gynec., & Obst. 79: 359, 1944.)

a distance of about three inches is resected along with the transverse process. The pleura and endothoracic fascia are peeled forward and the second and third intercostal nerves are pulled out and the anterior and posterior roots are sectioned intradurally proximal to the dorsal ganglia. A small segment of nerve is taken out. The dural defect may be sealed with a small piece of Gelfoam. All rami are cut. The sympathetic chain is cut below the third dorsal ganglion and this ganglion is removed. The chain is then tied, turned under, and sewed to muscle. For a gangrenous finger or toe, amputation is necessary.

Sudeck's syndrome is a vasomotor dysfunction of peripheral vessels usually following some minor trauma to the wrists or ankle. Various names have been used to identify the condition: chronic traumatic edema, trophic edema, traumatic angiospasm, post-traumatic osteoporosis, reflex causalgia-like states, peripheral trophoneurosis, reflex nervous dystrophy, acute atrophy of the bone. (See Chapter 21.)

The underlying cause is not clearly understood but the condition is thought to be due to the following sequence: pain due to trauma with resulting hyperemia, improper attention to the injury with voluntary splinting to avoid pain, stasis due to immobility, reflex vasoconstriction (due to pain or axonal reflex), increased pain due to swelling and tissue anoxia, more splinting, more stasis, etc. Undoubtedly there is some injury or at least chronic stimulus to the sympathetic as well as to sensory nerve fibers.

We have seen in Chapter 3 that the usual effect of injury is vasodilation. Since the same nerve fibers which are subservient to protopathic sensibility may cause opposite effects on stimulation, it may be assumed that the degree of chronicity of pain, together with local nerve involvement, makes up some of the complex components of the problem. In other words, there is a chronic stimulation of somatic and efferent vasoconstrictor fibers or dilator fibers if present.

The symptoms and signs include pain, which is localized but spreads as the syndrome progresses, hypersensitiveness, decrease in arterial pulsation, swelling, vasodilation and redness or cyanosis and coldness (vasoconstriction), the latter is less common, motor weakness, stiffness, and later bone atrophy.

Trophic changes are of two types: (1) The skin is cold, thin, and glistening, the superficial layers are denuded, and sweating is profuse. There is loss of hair, tapering of the digits like in Raynaud's syndrome, and clubbing of the nail; vasoconstriction is present; and the skin temperature is two to six degrees lower than in the normal extremity. (2) The more frequent type presents a warmer extremity, with more hair, edema, glossy skin, and no clubbing, although the skin may be dry and even scaly.

Treatment includes prophylaxis which means rest and immobilization for a suitable period for minor injuries and infections. The disease

usually responds to sympathetic block with 1 per cent procaine. However, the effect is not lasting as a rule, and if there is no response, then sympathectomy will not help. Recently tetraethyl ammonium bromide and Priscol have been used. If the syndrome is well advanced, sympathetic ganglionectomy is the procedure of choice. Those who believe that chronic vasodilatation is the cause attribute the relief from sympathectomy to an interruption of pain fibers. In those cases which are accompanied by vasoconstriction the patients are thought to receive the benefit from an increased blood flow. Indeed, warm moisture helps those with vasoconstriction and cold moisture is of benefit to patients with chronic vasodilation. Those with trophic changes are benefited, depending upon

Fig. 46.—Gangrene (dry), due to ergot poisoning. The patient, a woman aged 18 years, had a miscarriage and was given ergotamine tartrate by intramuscular injection.

restoration of blood flow to normal and therefore are helped by cold or warmth, depending on whether there is vasoconstriction (warmth) or vasodilation (cold). Not all cases can be explained on changes in blood flow and are either nerve phenomena or psychalgias. (See Chapter 28.)

Organic Causes of Gangrene.—

Arteriosclerosis.—Arteriosclerosis includes a group of chronic changes in the arteries which are identified pathologically as follows: (1) Atherosclerosis, which begins in the *intima* with splitting of the elastic fibers, some destruction of fibrous connective tissue and even muscle, and deposit of lipoids followed by fibrosis, hyalinization, atheroma, and

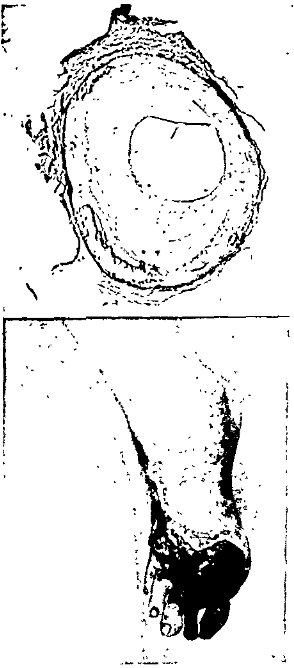

Fig. 47.—Arteriosclerotic (dry) gangrene (Mönckeberg's type). A cross section of a partially obliterated artery is shown. There are calcification of the media and thickening of the intima, with almost complete occlusion by the thrombus.

calcification. The deposition of lipids in the intima is dependent on local factors not clearly understood but thought to be related to defective fat metabolism. Atherosclerosis is a disease caused by the presence of an irritant which is thought to be an excess of cholesterol, in ester form, which is brought to the arterial intima in phagocytic cells rather than by inhibition. The absence of atherosclerosis in youth is said to be due to an effective removal of excess esters from the intima in the atheroma of infancy and puberty and at the sites of congenital abnormalities and injuries. Local thrombosis may occur at the site of the atheromatous plaques, giving rise to occlusion at the site of thrombosis or distally due to dislodgment, producing an occlusive embolism. The bifurcation of the aorta is a common site for the formation of ragged plaques leading to thrombosis and slow occlusion of the lumen. Thrombosis may also occur in the presence of dissecting aneurysm, arteritis and congenital narrowing. (2) Medial sclerosis (Mönckeberg), which is also called senile arteriosclerosis. It affects chiefly the smaller arteries such as the femoral, radial, temporal, popliteal, etc. The first change is a fatty degeneration of the muscle and elastic coat with necrosis and calcification. This is manifested as "corduroy" arteries if the calcific rings are separated or "pipe stem" if fused. These changes may be felt and also seen in the x-ray film as areas of calcification. (3) Endarteritis obliterans or deformans, which is an occlusion of the artery by connective tissue without atheroma or calcification. It is the same process as atherosclerosis but occurs in smaller vessels. The artery may become converted into the fibrous cord. (4) Diffuse arteriolar sclerosis (arteriocapillary), which is characterized by endothelial hyperplasia, hyalinization, and reduplication of elastic lamellae (Karsner). It is found in the arterioles of the kidney, liver, brain, gastrointestinal tract, skeletal muscle, adrenal gland, pancreas, and other organs but is not a cause of gangrene of the extremities. Clinically the term arteriosclerosis obliterans has been used to identify the type which leads to progressive occlusion of arterial lumina. It supplants the terms thromboarteriosclerosis obliterans, occlusive arteriosclerosis, arteriosclerosis with thrombosis, senile gangrene, diabetic gangrene, and endarteritis obliterans.

Symptoms and Signs.—Usually arteriosclerotic gangrene is seen as the Mönckeberg type which causes a gradual decrease in the blood supply of the extremity, producing dry gangrene or mummification. This is a slow shriveling process in which the part changes from a cyanotic color to black. The part is painful during this process. Finally a line of demarcation occurs between the living and dead tissues. Ordinarily there is some inflammatory response with hyperemia proximal to this line. Of course, there is no pulsation in the dorsalis pedis or posterior tibial or even in the popliteal artery as a rule. The atheromatous type may give rise to similar symptoms or if the thrombus becomes dislodged, there may be a sudden and dramatic change as is seen in embolic gan-

grene which may be "wet" or "dry." One of the earliest symptoms is an intermittent claudication. When exercised, the muscles of the leg demand more blood, and when this is not forthcoming, a painful spasm results. Slow occlusion of the aorta at its bifurcation gives rise to the following symptoms: pain in both legs and hips, effortless fatigability, and intermittent claudication.

Nocturnal cramps may simulate intermittent claudication, but the phenomenon is not limited to the aged or those who have peripheral vascular disease. It is observed in aged patients with arteriosclerosis that when the blood pressure falls due to rest and when in addition there is venous stasis due to lack of motion, a relative histanoxia occurs producing painful muscle spasm. This is seen in the second trimester of pregnancy and in young men and women apparently normal. This pain is like that of angina pectoris (Lewis). If at a certain level of work (metabolic demand) the oxygen available is insufficient, pain arises. Since the cramps occur while the person is at rest, the events are as previously stated or there may be other factors such as hypoglycemia

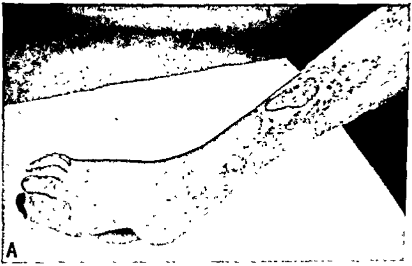

Fig. 48.—Early arteriosclerotic gangrene and varicose ulcer. Man aged 67 years. No pulsation of the dorsalis pedis or posterior tibial artery could be felt.

and hypocalcemia; either or both may induce muscle cramps, the former because oxygen is useless to working muscle cells unless there is enough dextrose to be oxidized and insulin to catalyse the reaction. Therefore diabetic patients on a diet providing too low a dextrose level have muscle cramps. The latter is seen in tetany to a marked degree. Often heat is used to relieve the cramps, especially in the aged with arteriosclerosis. This usually makes matters worse because tissue metabolism is increased, demanding more blood which is not forthcoming. Most of these patients have found that cold does not help either because blood holds its oxygen in cold, and if any normal collaterals are present they are forced into spasm. The patient therefore will get out of bed and walk for a few minutes, stimulating venous return and thereby breaking a vicious circle (see Chapter 17). Muscle cramps disappear promptly, permitting a resumption of sleep.

X-ray shows the calcification of the vessels which usually may be identified especially in the radial artery.

Tests for Peripheral Circulation.—*Arteriography* is useful in arteriosclerotic occlusion, embolism, thromboangiitis, vessel trauma to demonstrate the site of occlusion,

and the amount of collateral circulation; also, it demonstrates arteriovenous aneurysms and simple arterial aneurysms (the position of the sac and its degree of patency). It may also detect the presence of bone tumors (Shallow) and is useful as an aid in diagnosing venous occlusions. Usually 7 to 10 c.c. of Neo iopax, thorotrast, or Diodrast are injected into the brachial or femoral artery and then an x-ray film is made. This test, while very useful, is *not without danger*. Complications both local and general have been reported. In the *former* group may be mentioned hematomas, extravasations, and severe vasomotor reactions as well as local thrombosis with subsequent gangrene. The latter occur whether Thorotrast or organic iodine compounds are used. Hematemesis, severe anemia, decreased coagulability of the blood, and sudden death from respiratory failure have been reported. Necrosis of organs especially rich in reticulo-endothelial cells (liver and spleen) from Thorotrast is known, and its radioactivity may be maintained in these cells for years. There may also be erythematous eruptions, nausea, vomiting, cyanosis, and respiratory distress.

Oscillometry consists of applying a sphygmomanometer cuff and observing the differences in pulsation of the extremities, the amplitude, and the level at which no oscillations are seen. The instrument known as an oscillometer (Pachon) is especially made for the purpose. Obviously the extent of collateral circulation is not revealed by this test. *Venous return test.* The arm or leg is elevated to empty the veins. Then with the extremity in the horizontal position a blood pressure cuff is applied and inflated to about 60 mm. of mercury. Normally the veins fill in five to ten seconds. A delay implies partial arterial occlusion.

Changes in Skin Temperature.—If the body temperature is normal and if the room temperature and humidity are known, then the skin temperature may be accurately measured and compared with the opposite extremity. Mercury skin thermometers and an electrical device known as the Dermatherm are available for this purpose. It is useful when there is a sudden drop in one extremity or when great variations exist between the two extremities or between adjacent areas. A temperature rise after tests to relieve spasm may help estimate the amount of the spastic element.

Determination of the spastic element may be elicited by drugs, spinal or general anesthesia, local infiltration of the nerves to the part, sympathetic nerve block, sacral block, or artificial fever induced by foreign protein or typhoid vaccine; also, immersion of the hands in hot water (110° F. for thirty-five minutes) will normally cause the feet to reach a temperature of 90 to 92° F. Another test which is very simple is the application of the blood pressure cuff to the principal artery, inflating it to systolic blood pressure and leaving it in position for five minutes. When released a normal extremity will flush evenly in a few seconds. This will be delayed and uneven in diseased vessels. The intradermal injection of histamine, 0.1 c.c. of a 1:1000 solution, will not produce a flare if an insufficient pressure is present in the skin vessels or if spasm is severe. Another method for determining the spastic element is the use of drugs. Formerly tetraethyl ammonium chloride and tetraethyl ammonium bromide were employed to act as sympatholytic drugs. They did produce vasodilation but they had the disadvantage of having to be used subcutaneously or intramuscularly. Recently a newer product has been developed whose trade name is Priscol (Ciba). The drug is priscoline hydrochloride. It is a 2-benzylimidazoline hydrochloride. Its action is to produce vasodilation and to increase peripheral blood flow, and it is said to counteract the constrictive effect of epinephrine-like substances in the vascular myoneural junctions. The drug, of course, has a general effect, and it is apt to produce a general vasodilation with fall in blood pressure. Priscol may be given in 25 mg. doses and may be used orally or parenterally at three- to four-hour intervals. If there have been no distressing side effects, the drug may be increased to 50 mg.

For tests to determine the spastic element, 200 mg. are given in divided doses of 50 to 100 mg. every hour. After administration, the following tests help to evaluate the presence of the spastic element: (1) The skin temperature; a gross estima-

tion of the differences between extremities as well as between the distal portion of the extremity and the skin of the body may be done either with the back of the hand or with an electrothermometer. The difference in temperature between the toes and the abdominal wall or the fingers and the skin over the sternum should be greatly decreased *after the use of this drug*, and this change should occur within about five minutes after intravenous administration and twenty minutes after intramuscular injection and within forty-five minutes if given orally. (2) Dependent venous filling; if the patient is kept recumbent with his legs elevated at an angle of 45 degrees for a few minutes, normally the veins collapse. Blanching of the skin is greater, of course, in peripheral vascular disease where there is less blood in the extremity at all times. If the patient sits up, allowing his feet to hang over the edge of the bed, the skin flushes and the veins distend with blood. Ordinarily the veins will fill within about 10 to 20 seconds. If it takes a longer time, say 40 or 50 seconds, for the veins to fill completely, there is presumptive evidence of impaired arterial circulation. By the use of sympatholytic vasodilators and adrenolytic substances such as the drug mentioned, flushing time will be decreased as will also venous filling time. It is conceivable that in advanced arteriosclerosis Priscol may be harmful because blood may be shunted into vessels that do have a spastic element and thereby divert blood elsewhere than from the extremities. (3) *Oscillometric readings should be increased after vasodilators if the spastic element is present.*

Priscol comes in tablets of 25 mg. each or in vials of 10 c.c. with each cubic centimeter containing 25 mg. The other drugs previously mentioned which have been used to interrupt vasospasm by blocking the sympathetics are tetraethyl ammonium bromide or tetraethyl ammonium chloride. These drugs are given intramuscularly in the dose of 20 mg. per kilogram of body weight. A 10 per cent solution 100 mg. per cubic centimeter is used, and the maximal dose ranges from 1 to 1.2 Gm. Clinical symptoms and signs are, after all, most reliable. The maximal blood flow to the foot may be reduced to 50 per cent without symptoms or trophic changes; 67 per cent is apt to produce them.

Whereas in dry gangrene nature may ultimately perform its own amputation without death of the patient, in moist gangrene this usually does not occur. Dry gangrene may become moist after invasion by saprophytic organisms. Both types harbor pathogenic bacteria, the former usually fewer than the latter. The terms dry and moist are clinically descriptive and do not always indicate the cause or degree of infection. Indeed there may be no initial infection in some types of "wet" gangrene as in gangrene due to embolism. It is more common where infection plays an important role as in diabetic gangrene with infection or gangrene due to virulent bacterial invasion without primary vascular changes. The moistness of the part is due to the presence of lymph, blood plasma, serum, and exudate, depending upon its cause. In embolic gangrene a sudden occlusion with its concomitant spasm traps blood due to a decrease in vis a tergo, venospasm, or venous thrombus (here the "wetness" would be chiefly plasma). In infections which are primary the cause is exudation. The extremity turns deep purple and blebs form, and before the leg turns black it is very malodorous. The "wet" type is more dangerous because of the greater virulence of the infection.

Prevention and Treatment.—Present concepts do not point to a clear way of preventing arteriosclerotic gangrene. First a word of caution concerning surgery of any kind on the lower extremities of elderly

people. This should not be done without careful evaluation of the circulation. A gangrenous process often begins after minor operations such as bunionectomy, removal of ingrown toenail, trimming of corns or calluses, etc. Obviously the same warning applies to any peripheral vascular disease. However, in the pregangrenous stage much may be done to *alleviate pain, promote collateral circulation, and at least postpone the* development of gangrene. Since the extremities comprise about 56 per cent of the body surface and contain no vital organs, they are important in the regulation of body heat, rate of blood flow, and blood pressure. Improvement in their circulation is important not only to the extremity involved, but also to the body as a whole. The general condition of the patient demands careful attention.

In arteriosclerotic gangrene the element of spasm is minimal. Therefore, chemical vasodilators help very little. However, they may be tried. Alcohol may be given in repeated small doses by mouth, acetylcholine or papaverine hypodermically. The lumbar sympathetic ganglia may be injected with 1 per cent procaine (20 c.c.). If a favorable response (vasodilation) is obtained, lumbar sympathetic ganglionectomy may be done. Even though this does not prevent further involvement of vessels by the arteriosclerotic process, it does postpone the approach of gangrene and it does relieve pain, because pain results from a demyelinization of somatic nerve fibers caused by anoxemia due to poor vascularization. For the same reason motor nerves do not function properly and reflexes are impaired. Hot and cold contrast baths and elevation and lowering of the legs (vascular exercises) are helpful. Mechanical devices such as the glass boot have been advocated. This is a positive-negative pressure apparatus which is thought to "pull" out new collaterals and force a return of blood and lymph by the veins and lymphatics. The rationale is comparable to that of "Bier's hyperemia" methods. It is best used at room temperature. Many fear its use because of the possibility of (1) dislodging venous thrombi which may be present, (2) spreading infection if cellulitis is a complication, (3) actually causing arterial occlusion at the site of the cuff, if arteriosclerosis or endarteritis exists—a possibility which contraindicates the use of tourniquets during amputations in such states, or (4) actually traumatizing the poorly nourished skin, thereby favoring infection.

Another mechanical method which is very useful is that of intermittent venous occlusion. This is effective not only because of the increase in capillary pressure, but also because of the reactive hyperemia due to accumulation of metabolites, as described by Lewis and Grant.

Many devices are available which cause inflation (less than diastolic pressure, about 40 mm. Hg) for one to two minutes and then deflation for about one and one-half to two minutes. They are allowed to work continuously; that is, day and night. This increase in venous pressure is *transmitted back to the arterioles* or their collaterals, causing them to

open up or stimulating the formation of new capillary loops. If such pressure were too high or too long continued, the capillaries would rupture, causing deep hemorrhage and necrosis.

If the pressure were kept as high as the diastolic blood pressure continuously, a condition similar to Volkmann's contracture would follow. The cuff is therefore inflated (up to diastolic pressure or below) and then decompressed: that is, pressure is applied intermittently. Pressure up to systolic may cause a thrombus to form at the site of the cuff.

Ligation of femoral vein is indicated in chronic obstructive arterial disease before gangrene, ulceration, or infection occur. Glasser reports relief of pain in the majority of cases so treated. This procedure does not prevent gangrene but may delay it and afford relief. It is also effective in reducing the likelihood of pulmonary embolism following amputation. For slow occlusion, resection of the constricted area has been advocated by Leriche if sympathectomy does not relieve symptoms.

Treatment for Gangrene: Arteriosclerotic patients usually present themselves for treatment when gangrene of one or more toes has occurred. These should be amputated with local anesthesia and then treatment as previously outlined should be pursued. The wounds should be left open. Usually but not invariably this is a beginning which leads to more and more involvement of the foot and legs.

Two tests which serve as a guide for the site of amputation are (1) the determination of cutaneous temperatures and (2) production of histamine flare. The latter is by far the more reliable. Should no response to histamine occur, circulation is inadequate and $\frac{1}{10}$ c.c. of hydrochloride histamine or histamine acid phosphate in a 1:1000 solution should be given. The response occurs within five minutes and manifests itself by hyperemia and rise in skin temperature. This test is by no means infallible. In colored patients the rise in temperature must be the guid*ing sign. A word of caution concerning these tests should be made.* If they are positive, the stump may still fail to heal and if they are negative, good healing may yet be obtained if atraumatic surgery is used. When gangrene involves the foot and lower leg, amputation just above the condyles of the femur should be done. This is the site of election regardless of whether or not the popliteal artery is pulsating. However, the *best test is an incision in the lateral muscles of the leg without a tourniquet; if bleeding is ample, the stump will heal.*

We have frequently performed amputation below the knee in the hope of saving the knee joint and the upper third of the tibia; also through the foot so that the ankle joint may be saved. Subsequent amputations were necessary in many cases. With modern artificial legs, in this age group it is much better and safer to amputate high enough for healing to occur. A circular incision is made, without a tourniquet, the vessels are ligated, muscles are severed at a slightly higher level, and the femur is sawed about two to three inches above the skin incision. Muscles and

skin are loosely approximated. In a few cases lower leg amputations will be successful provided there is active bleeding when incision is made in the muscles. When in doubt, we begin our test incisions immediately above the gangrenous area and perform amputation at the first site of active bleeding. The patient is up and out of bed on the following morning.

Types of anesthesia: We have usually used a light ether anesthetic. Recently refrigeration anesthesia has been employed with success.

Cryo- or crymotherapy has been discussed in previous chapters. Its use in badly infected, gangrenous extremities has been a great help. The leg is wrapped with gauze around which are placed ice bags or ice water or ice. Cellular activity is suspended by this method. Absorption of toxins is reduced, bacteria do not grow, and pain is greatly relieved. Oxygen consumption of tissues can be reduced about 13 per cent for each degree centigrade. If, in addition, a tourniquet is applied, the oxygen demands are reduced sufficiently so that necrosis is prevented for many hours. Blalock has recently demonstrated experimentally that if a tourniquet is necessary, cooling an extremity prevents or at least lessens the chances for shock by curtailing the rapid loss of plasma into the injured extremity. In previous chapters some of the objections to cold were reviewed and especially when employed in inflammatory lesions. In gangrenous extremities the local effects which may inhibit inflammation and local immunity factors are not important. The greatest consideration is the improvement in the patient's toxic state, the reduced fever, and the chance to restore water balance and prepare the patient for surgery (especially in diabetic gangrene). After forty-eight to seventy-two hours operation may be safely attempted. Using this method Allen has performed amputations relying entirely on refrigeration for anesthesia. A narrow tourniquet is applied, and the entire extremity is packed in ice, and within two hours amputation may be done. A slight modification of this is the use of two tourniquets, two to three hours before surgery. One is placed immediately above the area of gangrene and the second above the site of the proposed amputation. It is applied to the stump postoperatively for several days.

We have used this method but prefer packing the leg up to the knee in ice for two to three days and then amputating quickly without a tourniquet under light ether anesthesia.

Our objection to the tourniquet-ice method is the necrosis of the stump distal to the tourniquet, making the process of healing very slow and potentially dangerous in debilitated patients.

Diabetic Gangrene.—Diabetic gangrene is a form of arteriosclerotic gangrene with or without infection. Since infection is more common in diabetic patients, this is apt to be a complication if not the cause of necrosis.

The arteries show a subintimal thickening and lipoid degeneration. This may extend well into the intima. However, there may be calcific changes in the media and necrotic fatty plaques. In any event, the vessel lumen is narrowed, and finally there is occlusion by secondary thrombosis.

Acute venous occlusion and phlebosclerosis are not as common in persons with diabetes as in those without diabetes. Diabetes is not always associated with arteriosclerosis, especially if the disease has been prop-

open up or stimulating the formation of new capillary loops. If such pressure were too high or too long continued, the capillaries would rupture, causing deep hemorrhage and necrosis.

If the pressure were kept as high as the diastolic blood pressure continuously, a condition similar to Volkmann's contracture would follow. The cuff is therefore inflated (up to diastolic pressure or below) and then decompressed: that is, pressure is applied intermittently. Pressure up to systolic may cause a thrombus to form at the site of the cuff.

Ligation of femoral vein is indicated in chronic obstructive arterial disease before gangrene, ulceration, or infection occur. Glasser reports relief of pain in the majority of cases so treated. This procedure does not prevent gangrene but may delay it and afford relief. It is also effective in reducing the likelihood of pulmonary embolism following amputation. For slow occlusion, resection of the constricted area has been advocated by Leriche if sympathectomy does not relieve symptoms.

Treatment for Gangrene: Arteriosclerotic patients usually present themselves for treatment when gangrene of one or more toes has occurred. These should be amputated with local anesthesia and then treatment as previously outlined should be pursued. The wounds should be left open. Usually but not invariably this is a beginning which leads to more and more involvement of the foot and legs.

Two tests which serve as a guide for the site of amputation are (1) the determination of cutaneous temperatures and (2) production of histamine flare. The latter is by far the more reliable. Should no response to histamine occur, circulation is inadequate and $\frac{1}{10}$ c.c. of hydrochloride histamine or histamine acid phosphate in a 1:1000 solution should be given. The response occurs within five minutes and manifests itself by hyperemia and rise in skin temperature. This test is by no means infallible. In colored patients the rise in temperature must be the guiding sign. A word of caution concerning these tests should be made. If they are positive, the stump may still fail to heal and if they are negative, good healing may yet be obtained if atraumatic surgery is used. When gangrene involves the foot and lower leg, amputation just above the condyles of the femur should be done. This is the site of election regardless of whether or not the popliteal artery is pulsating. However, the *best test is an incision in the lateral muscles of the leg without a tourniquet; if bleeding is ample, the stump will heal.*

We have frequently performed amputation below the knee in the hope of saving the knee joint and the upper third of the tibia; also through the foot so that the ankle joint may be saved. Subsequent amputations were necessary in many cases. With modern artificial legs, in this age group it is much better and safer to amputate high enough for healing to occur. A circular incision is made, without a tourniquet, the vessels are ligated, muscles are severed at a slightly higher level, and the femur is sawed about two to three inches above the skin incision. Muscles and

without a tourniquet and under light ether or sodium pentothal anesthesia. This should be of the "chop" or guillotine variety or if infection has not spread rapidly, the short flaps may be very loosely closed with one-half inch gap.

EMBOLIC GANGRENE.—Embolic gangrene may be associated with arteriosclerosis in which atheromatous plaques or thrombi become dislodged. Usually the vascular tree is normal. The causes are:

Heart Lesions.—(1) Mural thrombus in the left atrium due to (a) rheumatic heart disease with mitral stenosis and (b) degenerative heart disease with auricular fibrillation, (2) infarction of left ventricle from coronary occlusion, (3) thrombosis upon the heart valves in acute endocarditis, and (4) subacute bacterial endocarditis, (5) failing heart from any cause. In over 90 per cent of the cases of myocardial infarction, the ventricles (especially the left) are the site of thrombus formation. In rheumatic heart disease the thrombi are in the auricles and auricular appendixes. Cardiac mural thrombi are more common in older patients with auricular fibrillation and/or congestive heart failure.

Paradoxic or Cross Embolism: This refers to those which are originally in the venous system and come to lodge in the arterial side. This may occur in patent foramen ovale or patent interventricular septum where alteration of pressure may be higher in the right than in the left atrium or ventricle. Venous thrombi occur postoperatively or in various infections such as typhoid fever, pneumonia, diphtheria, malaria, puerperal sepsis, and influenza. They may follow fractures, operations, and infections in the chest.

Arterial Lesions: (1) Atheromatous plaques with thrombi, (2) trauma to an artery resulting in thrombosis with subsequent embolism, (3) aneurysm, and (4) inflammation. Thrombosis causing embolism may be due to inflammatory disease (thromboangiitis obliterans, periarteritis nodosa, mycotic arteritis); degenerative changes (arteriosclerosis); traumatic injury (cervical rib, gunshot or other penetrating wounds, contusions); and thrombosis without arterial disease (infectious diseases, heart disease, blood dyscrasias, ligation or suture of artery, idiopathic thrombophilia as seen postoperatively without apparent cause, and trauma).

Subacute bacterial endocarditis and auricular fibrillation are the most common causes. Often a "saddle" embolus lodges at the bifurcation of a vessel. If this occurs at the bifurcation of the aorta, both legs may have symptoms and the area of discoloration and coldness extends to the level of the umbilicus. Finally, a part of the embolus becomes dislodged, affecting one leg only and sparing the other. Recently we have had a case where the embolus divided, lodging in the common iliac bifurcations on both sides. The prognosis is better in all arterial occlusions if a large vessel is occluded, for it permits collaterals to form. It is serious in end vessels, such as the mesenteries, where gangrene is usually inevitable.

Immediately after an embolus lodges the affected vessel and the regional arterial tree go into violent spasm. The embolus may be smaller than the lumen of the artery but is trapped by its spasm. Within two

erly controlled in comparable age groups. However, there is a definite tendency for arterial change with calcification to occur earlier in persons with diabetes.

Symptoms and Signs.—There is usually a history of some trauma to the foot or some minor surgery inflicted by the patient in trimming corns or toenails. A small sore then results which is painless but fails to heal. The area becomes larger, finally involving one or more toes which gradually undergo shrinking as in "dry" gangrene with a definite line of demarcation. More often the same story is told as to the onset, but the process is more rapid with redness, swelling (wet gangrene), and lymphangitis. Soon large blebs which are purplish in color form on the plantar surface. Small joints become infected, as do the phalanges and metatarsals. This is followed by general cellulitis and septicemia. There is no pulsation in the dorsalis pedis and posterior tibial and often none in the popliteal.

Prevention and Treatment.—Diabetic patients must be instructed in the care of their feet. The slightest scratch should be regarded seriously and cared for by rest in bed, elevation of the extremity, and intermittent venous occlusion.

If infection is not present, a gangrenous toe may be amputated after a line of demarcation has formed. If infection is the cause of necrosis and collateral circulation is good, attention should be given the infection which may heal. The sulfonamides and penicillin are invaluable here. Moist hot packs are undesirable because of the trauma incurred by their application and the maceration of tissue which may result from prolonged soaks. Heat is not advisable for the same reasons plus those discussed previously (q.v.).

If infection and vascular occlusion are present, conservative measures should be tried. However, they will usually be unavailing because diabetes is difficult to control in the presence of infection and infection is not apt to subside in the presence of uncontrolled diabetes. As a practical course it is advisable even under such conditions to prove to the patient that local and conservative measures will not produce a cure. In rapidly spreading infection in the presence of vascular occlusion diabetic coma is apt to follow. This is extremely difficult to handle. Attention to water balance, blood and plasma transfusion, electrolyte control, and insulin are necessary adjuncts. In addition, penicillin should be given in large doses intramuscularly, 100,000 units every three hours. Conservative amputations should be tried but may fail because the stump will not heal. Certainly in gangrene of the toes or foot amputations like the Lisfranc (disarticulation of the tarsal and metatarsal joint), Chopart (disarticulation of the mediotarsal joint), or Syme (disarticulation of the ankle joint) should be given a chance. Above the ankle it is far safer and better to pack the extremity in ice for twenty-four to forty-eight hours then do an amputation just above the condyles

vasoconstriction, stasis, and anoxemia of the part, thereby causing irreversible changes to capillaries and cells. Usually the part is protected by "mechanic's waste" as a pad, surrounded by bandage, and exposed to room temperature. If amputation is anticipated, cold should be used as described under arteriosclerotic gangrene.

If the patient is seen early, say within six to twelve hours, embolectomy should be done. We have successfully removed emboli of the aorta after twenty-three hours. Some surgeons state that this procedure may be

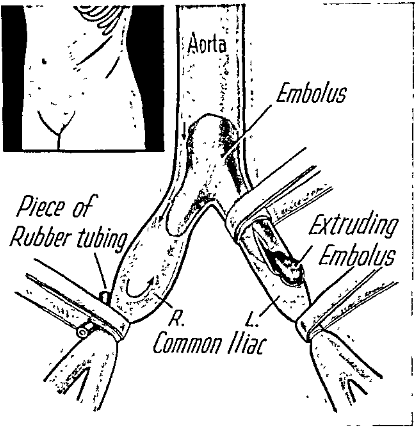

Fig. 49.—Embolectomy. Diagram of procedure used in a recent case of saddle embolus at the bifurcation of the aorta. M. G., a woman age 62 years, had auricular fibrillation. The large embolus caused bilateral occlusion of the iliacs. Within six hours following the onset of symptoms the right leg began to show signs of returning circulation. The left leg was cold, mottled, and slightly cyanotic. The color change and temperature change extended up to the umbilicus on the left side. The diagnosis was obviously a saddle embolus at the bifurcation of the aorta and the patient was operated upon at once.

Note the incision is a modified McBurney incision on the left side. The peritoneum was pulled medially. The aorta and both common iliacs were exposed. Umbilical tape was placed around the left common iliac above and below the proposed site of incision and around the right common iliac. All tapes were tightened. A longitudinal incision was made in the left common iliac artery and the left lower tape was released. Bleeding was free. Then the upper left tape was released, but no bleeding occurred for a few minutes. Soon the force of the blood stream, together with the dilation caused by the increased pressure below, forced the saddle embolus into the left common iliac where it found free egress from the longitudinal incision. It was prevented from descending down the artery by the distal tape. After a free flow of blood occurred from the proximal side, the upper tape was pulled taut and the artery was flushed with heparin solution. The incision was then closed with interrupted mattress eversion suture of 0000 silk. This patient made an uneventful recovery. Circulation was restored to both legs. Pulsations ultimately occurred in both legs, although the left dorsalis pedis did not show pulsations for approximately three weeks. (Case of Dr. R. M. Vandivier.)

hours a propagating thrombus distal to the embolus begins to form. This may be so extensive after a few hours that many collaterals are occluded so that even the removal of the embolus would not permit adequate circulation for the extremity. It is because of this phenomenon, together with the effect of spasm on the arterial wall, that sympathetic nerve block has been advocated.

Symptoms and Signs.—The symptoms and signs are first those of the underlying condition. Pain is usually present. It is sudden and severe, especially if the patient is ambulatory. It extends along the entire leg distal to the embolus and is probably due to vasospasm and muscle ischemia. Therefore it is more prominent in active muscles than in those which have been at rest in bed. Peripheral pulses are absent, the leg or arm is pale with scattered areas of cyanosis, and it is cold, with parasthesia, diminished reflexes, and some paralysis. The embolus is usually located in the first bifurcation of the principal arteries above the upper limit of physical findings. The area in between is normal due to ample collateral circulation. After a time even these vessels may become thrombosed, causing an increase in the area involved by gangrene; the gangrene is usually dry, especially if blood flow is not entirely arrested at once. Often it is wet with the formation of large bullae.

Treatment.—A sudden occlusion of an artery, with vasospasm of collateral vessels, will so decrease the vis a tergo of the blood that stagnation will occur in the veins, which stand out and soon become thrombosed. Usually the vessels are healthy except for those affected. Spasm, therefore, plays an important role. There is an emergency so far as the extremity involved is concerned. If it can be nourished until collaterals form, the leg may be saved. It is here that the glass boot or pavex machine, if used early before thrombi form or infection occurs, may help. Intermittent occlusion is much better. The surgeon should be slow to amputate because he must (1) improve the general condition of the patient, which is apt to be serious; (2) allow venous thrombi to become fixed, so that they will not be dislodged and carried into the blood stream (this and the possibility of spreading infection make use of pavex dangerous); (3) permit collateral circulation to form; (4) allow infection to localize; (5) allow nature to repair damaged tissue as far down as possible with the aid of new collaterals.

The extremity should be elevated so that edema of the muscles will be lessened. It is argued by some that elevation makes the blood flow through narrowed arteries against gravity. Since muscle demands far more blood than skin or subcutaneous tissue, it becomes edematous when circulation is slow or stasis occurs in veins. Edema, then, results, preventing the entrance of blood except under considerable pressure. Heat should not be used below the site of occlusion. This increases the metabolism of the part, calling for more blood which is not forthcoming. Heat above the site may improve collaterals. Cold should not be used. True it does decrease the demand for blood, but it may increase

gical treatment because the uninvolved vessels carry the blood supply; namely, radial and ulnar, dorsalis pedis, and posterior tibial.

After eight to ten hours the embolus becomes attached to the intima and antispasmodics may be used or the vasoconstrictors inhibited to accomplish vasodilation and stimulate collateral circulation. The following measures have been employed:

(1) Papaverine hydrochloride, ½ to 1 grain (0.03 to 0.06 Gm.), intravenously repeated at hourly intervals if necessary during the first twelve hours; continuing dose is ⅓ grain intramuscularly every six hours, (2) paravertebral block of the sympathetics with 1 per cent procaine, or sympathetic ganglionectomy, (3) actual excision of the portion of the artery containing the clot (Leriche) if twenty-four hours have elapsed since the occlusion or if the endothelium under the embolus is severely damaged or if gangrene threatens despite embolectomy.

Embolectomy is done under local, spinal, or general anesthesia. It should be done at the earliest possible moment through a liberal exposure. Wide umbilical tape is placed around the artery distal to the embolus to prevent its dislodgment distally. The artery is mobilized, and the adventitia is infiltrated with procaine and stripped off for a liberal distance. A proximal temporary holding tape is now placed around the artery. A longitudinal incision is made between encircling ligatures or special clamps or both, and the clot is gently "milked" out or allowed to come down by temporary removal of a proximal clamp or sucked out by catheter. Great care is exercised not to injure the intima. The clamps are then removed and the tapes loosened, and if a free flow of blood occurs from the proximal and distal portions of the artery, it may be assumed that the lumen is patent. The tapes are again tightened. Through the incision which has been made in the vessel between the occlusive tapes, the interior of the artery is flushed with 100 mg. of heparin dissolved in 10 c.c. of physiological saline solution; then another 100 mg. of heparin is dissolved in 10 c.c. of physiological saline and is introduced above the proximal occlusive ligature. This is acomplished by loosening the tape temporarily and occluding the artery with the fingers. The solution is injected and then the occlusive ligature is quickly tightened. This is done with the hope that thrombosis will not occur at the arterial suture line or the site of the anastomosis. The artery is then closed with interrupted sutures of 00000 silk, approximating intima to intima as described in Chapter 3. Following the operation, heparin may be given by the intermittent intravenous method or by the continuous intravenous method. If the former is used, the recommended dose is 50 to 100 mg. of heparin every four to six hours intravenously until coagulation time has been prolonged to about fifteen minutes. Another method of administration is the continuous intravenous method whereby the solution is given in 5 per cent glucose or physiological saline to which 100 to 200 mg. of heparin have been added per liter. About 20 to 25 drops are

of doubtful value, especially in small arteries like popliteal, because there will be a tendency for local thrombosis as a result of intimal irritation by the embolus and by its removal. It is true that collaterals may form quickly and abundantly. The immediate relief of arterial spasm is stressed by most authors. One may question the rationale for this since vasoconstriction is a protective mechanism in the presence of an embolus (a) to prevent entrance of small embolic fragments into smaller vessels less capable of forming collaterals and (b) to hasten the formation of collaterals by increasing proximal hydrostatic pressures. Preoperative sympathetic nerve block and spinal anesthesia and even papaverine may cause relaxation of the artery distal to the embolus, permitting a fragment to slip down into much smaller branches in which surgery is less effective, and if surgery is not done, collaterals are less apt to form. It should be noted, however, that the embolus becomes fixed in a few hours Antispasmodics and sympathetic block may be used before this time as a *diagnostic* procedure provided that embolectomy is to be done immediately.

Fig. 50.—Embolic gangrene (wet gangrene with infection).

This is permissible because vasospasm proximal to the embolus makes localization of the embolus difficult. There are other difficulties in localizing an embolus because collateral circulation may make the embolus appear more distal. The propagating thrombus peripheral to the embolus also confuses in the same way. The heart is frequently irregular and feeble in its beat, making the pulse difficult to detect.

Emboli usually lodge at bifurcations or divisions of arteries because their lumina become smaller at such points. Skin temperature changes provide a helpful but very unreliable guide. Usually if the popliteal is involved, the line of coldness is found above the ankle; an embolus at the bifurcation of the femoral shows this line at the junction of the middle and lower thirds of the thigh; and if in the common iliac, the line is at the junction of the middle and upper thirds of the thigh; if at the aortic bifurcation, the cold area extends to the level of the umbilicus. The arm behaves in a similar way. Emboli in paired arteries rarely require sur-

and other internal vessels, even in the retinal blood vessels, but this is rare even in late cases. The upper extremities are not involved as often as the lower. Arteries and veins after thrombosis may recanalize, giving rise to periods of remission and exacerbation. Smaller and larger vessels may be simultaneously involved. After the organization of the thrombus the walls of arteries and veins become thickened and infiltrated involving the accompanying nerve. The femoral and anterior tibial arteries are most commonly involved. Unlike arteriosclerotic gangrene, the process begins very insiduously with the formation of a small ulcer and with general thickening of surrounding tissue rather than shrivelling of the part.

Ulcers are apt to come and go. Often the patient states that the ulcer started by trimming a toenail too short or cutting a corn. Two of our patients had small burns of the dorsum of the foot and one sustained frostbite. A good rule to remember is that all patients should have a

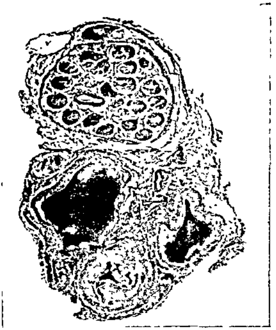

Fig. 51.—Buerger's disease. Cross section, showing the fibrosis around the arteries, veins, and nerve. Note the thrombi in the thickened vessels, obliterating their lumina.

careful examination of the extremities before minor surgery of the feet is attempted. In the younger group thromboangiitis or diabetes may be present; in the older, arteriosclerosis with impending gangrene. Patients with diabetes as well as others in these groups must be carefully instructed as to the care of their feet—the slightest injury or operation may start the formation of the ulcer with subsequent spread of the area of necrosis.

A thrombosis of an artery or vein involving the nerve presents a trying problem because of excruciating pain. Since a larger vessel is usually involved, there is good chance of a collateral circulation forming, if the patient can tolerate the pain. These men are young, usually heavy smokers, with hyperactive sympathetic nervous systems. *Intermittent*

given per minute, the total dosage being about 200 to 240 mg. per twenty-four hours. A third method is the intermittent intramuscular method whereby the drug is given intramuscularly about 100 mg. every eight hours or about 1 mg. of heparin per pound of body weight initially and subsequently 0.5 to 0.7 mg. per pound of body weight. We have used heparin as Depo-heparin sodium made by Upjohn in the following way: An initial dose of 200 mg. of heparin is given immediately after surgery. Usually this plus the heparin which has been injected intra-arterially is sufficient for an initial dose. The coagulation time is tested four hours after surgery and if necessary the aqueous heparin sodium is given intramuscularly in the dose of 100 mg. Usually, however, this will not be necessary because the Depo-heparin maintains a prolonged coagulation time for approximately forty-eight hours. In the past we combined this method with Dicoumarin which was given orally, using an initial dose of 300 mg. and then repeated as needed at four- to eight-hour intervals. However, Dicoumarin is perhaps more toxic and must be checked by prothrombin time, whereas heparin may be checked by simple coagulation time method. Therefore, we have been using the combined preparation of aqueous heparin and the Depo-heparin and depending upon this for our effect. The Depo-heparin is then given every other day for a period of about seven days, sometimes longer, depending upon the recurrence of emboli or the indications. See Chapter 13.

The approach to the bifurcation of the aorta is made through a left lateral oblique incision as for lumbar ganglionectomy. The peritoneum is retracted to the right.

Thromboangiitis Obliterans (Buerger's Disease or Presenile Gangrene).—This usually occurs in the lower extremities of middle-aged and younger persons. In this disease both the arteries and veins are blocked by thrombi. The nerve is also involved, producing excruciating pain. Pulsation is absent in the dorsalis pedis and the posterior tibial artery.

Etiology.—The cause of this disease is not known. Indeed it may be a combination of vascular diseases. There is, however, one significant probable cause and this is smoking. The effect of smoking on peripheral vascular disease is probably due to vasoconstriction caused by nicotine or the repeated short periods of anoxemia incident to the inhalation of smoke. This is shown by pallor, reduced temperature, and lowered volume of the extremities after smoking. The disease has been observed in a 15-year-old boy who was a heavy smoker.

There is first an arteritis, an inflammation of unknown etiology, with almost immediate thrombus formation. Sometimes a phlebitis migrans (migratory type) precedes or accompanies the disease. The extremities go through color changes, due to temperature changes. When allowed to hang down, the extremity is very painful and red (erythromelalgia). Buerger's disease is differentiated from arteriosclerotic gangrene by the younger age of the patient, the intractable pain, the low blood pressure, and the x-ray picture (absence of calcification). The disease may occur in the abdominal

salt solution intravenously, and sodium tetrathionate, 1 Gm., with sodium thiosulfate, 0.6 Gm., in 10 c.c. distilled water, to increase the oxygen content of the blood (chemical and mechanical), and rest. Pain may be controlled by injecting the sensory nerves to the part with alcohol. *Morphine* is not given because of the danger of addiction. If the patient can "weather the storm" of pain, he may avoid gangrene and amputation or at least postpone it. Sympathectomy is of value in many cases. The sympathetic ganglia should be injected with 20 c.c. of a 1 per cent procaine solution. Usually the first lumbar is all that is necessary, but if there is no response, the second and third may be injected also. A favorable response includes return of pink color, warmth, and absence of sweating. Each toe should be examined carefully. If a toe remains cold

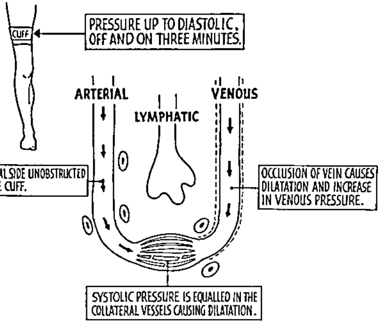

Fig. 53.—Diagram illustrating the effect of intermittent venous occlusion in the treatment of organic disease of the arteries. The pressure must not exceed diastolic, for it would not only interfere with the inflow of blood, but might damage the diseased vessel as well. The optimum pressure is about 40 mm. Hg on for 1½ to 2 minutes and off for about the same time This varies in different cases. The treatment may be continued night and day, without disturbing the patient

and blue and moist, sympathectomy will hasten gangrene just as heat does, but it will permit an amputation of the digit with a good blood supply to the stump. If the response is good, sympathetic ganglionectomy is done—first, second, and third dorsal for the arms and second, third, and fourth lumbar for the legs. Thrombophlebitis is a common complication of sympathetic ganglionectomy (4 per cent) in the heparin-resistant phase.

The treatment after gangrene has occurred is amputation. In this disease as much tissue as possible should be saved because all of the vessels are not diseased. Amputation of a gangrenous toe may be followed

claudication (a limp that develops upon exercise, due to the demand for more blood to the muscle than the crippled circulation can supply) is an early and annoying symptom. Intra-abdominal thromboangiitis obliterans causes intermittent intestinal claudication which manifests itself as severe cramping pain after eating. "White, red, and blue toes," due to the effects of temperature or dependent position, are also a warning sign.

Treatment.—The treatment at this early stage is the elimination of smoking (chemical?), the use of intermittent venous occlusion, vascular exercises, and antispasmodics (spasm), excessive amounts of 5 per cent

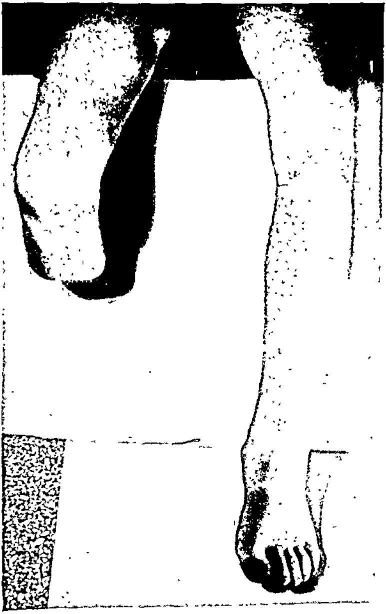

Fig. 52.—Buerger's disease. The patient is a young man aged 28 years. The *right* leg had been amputated previously. Note the deep color of the foot (erythromelalgia) when hanging in a dependent position. There is gangrene of the big toe and second toe. No pulsation in the *dorsalis pedis or posterior* tibial arterie. The popliteal can be felt faintly. There is excruciating pain. Amputation was ultimately done.

No pulsation in the dorsalis pedis or posterior tibial arterie. The popliteal can be felt faintly. There is excruciating pain. Amputation was ultimately done.

Local Causes.—

1. Increased hydrostatic pressure—thrombophlebitis or phlebothrombosis, varicose veins (involving the deep as well as the superficial veins), arteriovenous fistula, cicatricial occlusion as is sometimes seen following radical mastectomy; orthostatic edema occurs in old and debilitated patients or after prolonged immobilization of the extremity in a cast as in fractures.

2. Obstruction to the lymphatic return occurs in perilymphatic fibrosis from malignant disease, in filariasis due to the mechanical irritation of the Filaria worm in the lymph channels, cicatricial occlusions from ulcers, burns, or other injuries and from congenital anomalies of lymph vessels, lymphedema praecox or congenital lymphedema (hereditary or familial—Mulroy's disease, and simple types which affect only one member of a family).

3. Increased capillary permeability is due chiefly to infection.

Edema in infections (see Chapter 5) is due to an increased augmented permeability and the resultant increase in plasma protein in the tissue spaces. Reabsorption is prevented by the higher than normal osmotic pressure of the tissue spaces and also by thrombosis of blood and lymph capillaries. Heat causes increased vasodilatation and therefore the exudation of more plasma into the involved area, thereby aiding localization. From our previous discussion it is apparent that pressure bandage is contraindicated because it prevents adequate plasma bathing of tissue spaces and forces absorption of toxic material before local or systemic immunity is established. Active motion is also contraindicated because it too forces proteins into the lymphatics and aids in this propulsion. In addition there is the danger of dislodging thrombi. Elevation of the infected extremity is indicated because it limits venous stasis and edema and permits lymphatic absorption in an orderly manner. Therefore, rest and elevation of the part are favorable aids in the management of excessive inflammatory edema. Normally if 5 c.c. of normal salt solution is injected intradermally it should disappear in forty five minutes. In edema it will disappear more rapidly (due to high osmotic index of the fluid); in anasarca, almost immediately (McClure Aldrich test). The disappearance time sharply decreases just before or coincident with edema and increases preceding the edema or with its subsidence.

4. Combinations. In phlegmasia alba dolens there is probably venous and lymphatic obstruction. Acrocyanosis and Raynaud's disease may cause edema due to a decreased vis a tergo and therefore venous stasis or local tissue anoxia or capillary dilatation with increase in capillary permeability. In cellulitis there may be associated lymphedema. Unilateral edema of the extremities is usually due to (1) venous obstruction, (2) lymphatic stasis (congenital or acquired), (3) mixed venous and lymphatic obstruction, (4) arteriovenous fistula (congenital or acquired).

Swellings *not due to edema* in *one* extremity are seen in (1) pseudohypertrophic muscular dystrophy, (2) neurofibromatosis, and (3) tuberous sclerosis (see Chapter 16). Swellings not due to edema in *both* extremities are due to lipedema or abnormal distribution of fat in the lower legs for which condition dieting and exercise is indicated.

by complete healing. If gangrene or sepsis is present, a higher amputation is necessary. This may be below the knee at the site of election or through the condyles. Gritti-Stokes amputation is the best type because it gives a good weight-bearing surface in a young person who will need it.

Edema of the Extremities

Edema prevents the normal interchange of nutrient material and waste products between the blood tissue cells and therefore predisposes to infection and ulcers.

Edema of the lower extremities may be due to the following causes: (1) decreased osmotic pressure of the blood, (2) increased hydrostatic pressure in the capillaries, (3) increased permeability of the capillary wall, (4) obstruction to the lymphatic return (see Chap. 11), (5) combinations of the foregoing, and (6) miscellaneous.

The causes may be further divided into general and local. The more common varieties are as follows:

General Causes.—

1. Decreased osmotic pressure—nephrosis, malnutrition, hemorrhage, chronic infected areas, or any condition producing hypoproteinemia; an increased amount of saline or other crystalloids diluting plasma proteins; salt block. (Chapter 11.)

2. Increased hydrostatic pressure—cardiac decompensation, ascites with incompetent deep and superficial veins in the legs.

3. Injury to capillary walls—nephritis, organic arterial disease where there are asphyxia and capillary dilatation, excessive heat which causes great peripheral dilatation, allergic states such as angioneurotic edema, vitamin deficiencies such as scurvy, toxemias due to chemicals such as arsenic, etc.

4. Combinations of foregoing as in arteriosclerosis with failing heart, etc.

5. Miscellaneous causes: (a) *Myxedema* is probably due to an accumulation of a semifluid albuminous substance in the tissue spaces. The method of accumulation is not definitely known; however, in experimental myxedema a high protein diet increases the edema, whereas a low protein-high carbohydrate diet increases it. This is thought to be due to an increased capillary permeability, permitting plasma to accumulate in the tissue spaces. A high protein diet would simply increase the intercellular osmotic pressure, attracting more water into the intercellular spaces. (See Chapter 22.) (b) *Hyperthyroidism.* Edema may result from the vasodilation and associated high systolic blood pressure. It may, however, be due to a hypoproteinemia which results from the enormous demands for food or thiamine chloride deficiency. A high protein diet with vitamin B complex improves the edema by increasing the osmotic index of the blood.

Atherosclerosis

Age and sex	60 years or over as a rule; male or female	Any age; male or female	Presenile, 35 to 40; usually men	Young—under 40, usually female	55 or over; male or female
Onset of symptoms and type of symptoms and signs	Gradual onset with *increasing pain; sensitivity to cold*; pallor, atrophy; absence of vasomotor response; coldness, numbness; bluish mottling; absence of pulsation in posterior tibial and dorsalis pedis; brown, purple, or black discoloration	Sudden agonizing *pain; muscles rigid;* foot and toes white, then blue, then black; no pulsation; saddle embolism may give symptoms in both legs	Pain, gradual onset; *passive congestion;* deep red or purple discoloration; ulcers about tips of toes or nails; infection common; no pulsation in post-tibial or dorsalis pedis; vasomotor response may be present	Slow—gradual atrophy *made worse in cold;* vasomotor response great; gradual atrophy of fingers, ulcers, and then gangrene; then secondary infection; pulse good	Rapid progress—red *infected area with* septic arthritis, osteomyelitis, cellulitis lymphangitis; slight pain; pulse absent in dry type may be present in wet or infected type
Laboratory aids, x-ray, etc.	High systolic diastolic, blood pressure; x-ray shows calcification .	X-ray negative	X-ray negative except atrophy of disease; low blood pressure	X-ray negative except atrophy	Blood sugar; urine; osteomyelitis shown by x-ray

TABLE IV

DIFFERENTIAL DIAGNOSIS OF COMMON VASCULAR DISEASE CAUSING GANGRENE OF THE EXTREMITIES—PERIPHERAL VASCULAR DISEASES

DISEASE	OBLITERATING ARTERIOSCLEROSIS	EMBOLISM	THROMBOANGIITIS OBLITERANS	RAYNAUD'S DISEASE	DIABETIC
Underlying morbid anatomy	Atherosclerosis (intimal); medial sclerosis (Mönckeberg); arterial tuberculosis	Atherosclerosis	Inflammatory with thrombus affecting arteries, veins, and including nerves; large or small vessels may be affected	Sustained vasospasm; perhaps dilation of deep pulmonary arch; finally sclerosis of vessels, fingers and toes	Lipoid deposits in middle coat of medium-sized arteries with calcification (Mönckeberg), also intimal thickening; frequently infected
Associated or causal diseases	Generalized arteriosclerosis; cause unknown (?)	Subacute bacterial endocardiac failure, auricular fibrillation, and mural thrombus in left auricle due to endocarditis	Erythromelalgia; phlebitis migrans	Syphilis; severe secondary anemia; acrocyanosis; emotional instability; sclerodactylia; scleroderma	Trauma to feet; surgery to toes; diabetes hard to control in presence of infection
Type and extent of gangrene	Dry; one or more toes, foot, sometimes lower leg	May involve lower leg or arm; wet often; dry rarely; obstruction higher than gangrene due to collaterals	Wet; toe or entire foot, arms and legs may be involved	Usually hands—both; rarely feet	Dry or wet; one or more toes or entire foot or leg
History	Nocturnal leg cramps; rarely intermittent claudication	The primary condition	Intermittent claudication; phlebitis migrans; heavy cigarette smoker; exacerbation in cold; remission in warm weather	Color changes—white, red, purple, then red	Usually some trauma or operation—otherwise no warning

Atherosclerosis

Age and sex	60 years or over as a rule; male or female	Any age; male or female	Presenile, 35 to 40; usually men	Young—under 40, usually female	35 or over; male or female
Onset of symptoms and type of symptoms and signs	Gradual onset with increasing pain; sensitivity to cold; pallor, atrophy; absence of vasomotor response; coldness, numbness; bluish mottling; absence of pulsation in posterior tibial and dorsalis pedis; *brown, purple, or* black discoloration	Sudden agonizing pain; muscles rigid; foot and toes white, then blue, then black; no pulsation; saddle embolism may give symptoms in both legs	Pain, gradual onset; passive congestion; deep red or purple discoloration; ulcers about tips of toes or nails; infection common; no pulsation in post-tibial or dorsalis pedis; vasomotor response may be present	Slow—gradual atrophy made worse in cold; vasomotor response great; gradual atrophy of fingers, ulcers, and then gangrene; then secondary infection; pulse good	Rapid progress—red infected area with septic arthritis, osteomyelitis, cellulitis lymphangitis; slight pain; pulse absent in dry type may be present in wet or infected type
Laboratory aids, x-ray, etc.	High systolic-diastolic, blood pressure; x-ray shows calcification	X-ray negative	X-ray negative except atrophy of disease; low blood pressure	X-ray negative except atrophy	Blood sugar; urine; osteomyelitis shown by x ray

Differential diagnosis of chronic lymphedema and chronic postphlebitic edema may be made on the following data:

In lymphedema there is very little disappearance of swelling on rest and elevation of the limb; in postphlebitic edema the patient usually reports a great reduction of swelling after a night's rest. In the former the superficial veins are normal; in the latter condition they are prominent and there is an increase in venous pressure. Ulceration and pigmentation of the skin is often present in the latter but not in the former and the swelling is soft and pitting in venous edema, whereas it is firm in lymphedema.

TABLE V

DIFFERENTIAL DIAGNOSIS OF CHRONIC LYMPHEDEMA AND CHRONIC POSTPHLEBITIC EDEMA
(After Barker and Allen: Proc. Staff Meet., Mayo Clin., 1940.)

IMPORTANT DIFFERENTIAL CONSIDERATIONS	LYMPHEDEMA*	POSTPHLEBITIC EDEMA†
Consistency of swelling	Brawny and firm	Soft; pits easily
Disappearance of swelling after elevation of limb	Slow and may be incomplete	Usually complete in 36 hours
Superficial veins	Normal	Usually prominent
Ulceration or pigmentation of skin; eczema; varicose veins	Always absent	May be present
Venous pressure	Normal	Increased

*May result from or be associated with cellulitis.
†May result from deep thrombophlebitis.

The differential diagnosis of acute cellulitis and acute thrombophlebitis are listed by Barker and Allen as shown in Table VI.

TABLE VI

DIFFERENTIAL DIAGNOSIS OF ACUTE CELLULITIS AND ACUTE THROMBOPHLEBITIS
(After Barker and Allen: Proc. Staff Meet., Mayo Clin., 1940.)

IMPORTANT DIFFERENTIAL CONSIDERATIONS	ACUTE THROMBOPHLEBITIS		ACUTE CELLULITIS
	SUPERFICIAL	DEEP (ILIOFEMORAL)	
Fever, temperature	Rarely exceeds 100° F. (37.7° C.)	Rarely exceeds 101° F. (38.3° C.)	As high as 106° F. (41.1° C.), unusually high
Chills	Absent	Absent	Frequent
Recurrence in same region	Uncommon	Uncommon	Common
Edema or enlargement	Absent	Common	Common
Evidence of venous congestion*	Usually absent	Common	Absent

Palpable thrombosis of veins	Present	Usually absent	Absent

*Varices and prominence of superficial veins.

Treatment.—The treatment of edemas in the extremities will depend upon their cause. These discussions will be found under their respective headings throughout the book. Two examples may be cited.

If the obstruction is on the venous side, there will be an increase in hydrostatic pressure, causing edema. After the danger of dislodging a thrombus is over (four to six weeks), a tight bandage should be applied over the entire extremity. This increases the intercellular tissue pressure and the capillary blood pressure until it equals the tissue pressure. Filtration from the veins or into them cannot occur; however, since the osmotic pressure in the capillaries remains unchanged, fluid will be absorbed by the capillaries and lymphatics and ultimately the edema will be reduced. In addition, elevation of the extremity may be used to aid in its reduction.

The cause of swollen arms after radical breast operations is probably due in part to venous obstruction, although the lymphatic return may also be impaired. Homans and also Drinker and Fields have discussed the problem of lymphatic edema. They are of the opinion that it is very difficult to produce lymphedema experimentally or postoperatively by obstruction of the lymphatics alone. Homans believes that in phlegmasia alba dolens there is some lymphatic involvement with thrombophlebitis. The edema is due in part to the accumulation of protein material in the tissue spaces. The osmotic pressure in these spaces is increased, thereby preventing reabsorption of solutes and colloids by the blood capillaries. Increasing tissue space hydrostatic pressure by bandage forces proteins and crystalloids into the lymph capillaries. This stimulates the normal method of lymph movement, in which muscular contraction and arterial pulsation provide the only propelling force causing flow past the valves in the lymphatics. In the aged who are kept in bed for long periods of time, there is venous stasis (see Chapter 17). This is due to lack of the muscular activity upon which the venous return partially depends. Active motion tends to prevent this. Moreover, intermittent bandaging after mobilization of the patient may prevent the dependent edema which is caused by stasis when the patient resumes the upright position.

Intractable lymphedema which does not respond to conservative measures must be treated by plastic operations. These are done by turning back broad flaps which include the aponeurosis and which expose bone, muscles, and tendon sheaths. The operation includes one-half the circumference of the extremity. Then the lymph-soaked fibrous tissue and sclerosed fat are cut from the deep surface of the flaps which are left very thin. The other half of the operation may be done at a later date. This should be postponed for several months so that the flaps previously made will be healthy and withstand suturing of the new flaps. The first stage is usually anteromedial and the second stage is anterolateral.

The operation is done with a broad tourniquet so that a bloodless field is maintained. Communicating veins should be spared insofar as possible. The lateral sural branch of the common peroneal nerve should not be cut since it supplies the outer side of the foot and heel. At a later

time if the foot is still edematous, this can be treated in a similar manner at a third operation. Should the skin be ulcerated and infected, these operations must not be done because the flap will slough. Here it is better to excise large masses of tissue and then when granulations are healthy apply split-thickness grafts. Should the above measures fail, amputation must be done.

GANGRENE OF INFECTIOUS ORIGIN

1. Gas gangrene is discussed elsewhere (see Chapter 4). The bacterial toxin destroys wide areas of tissue and the effect is aggravated by the devitalizing effects of gas.

Since gas-producing anaerobes are normally present in muscles, the fact that there is crepitation does not mean impending gangrene. Very often air is absorbed without any clinical symptoms. In all severe injuries the wound should be cleaned, débridement done, and the wound left open. Tourniquets should not be used. By decreasing

Fig. 54.—Gas gangrene of the hand and forearm.

the oxygen supply they favor the growth of anaerobes. Should crepitation develop, this must be carefully observed. If there are no local spreading and no general symptoms, it will subside. X-ray treatment has been advocated by some. However, its remedial effects have not been definitely established. Gas gangrene is probably due to anaerobic bacilli and streptococci in symbiosis. Therefore sulfanilamide is helpful. In all badly contaminated accidental wounds polyvalent antitoxin of the gas bacilli group should be given, together with tetanus antitoxin, even if tetanus toxoid has been given, as a prophylactic measure. *Experimental wounds inoculated with clostridium welchii, Cl. septicum, Cl. novyi, or Cl. sordellii* caused death in guinea pigs within twenty-six hours. When inoculated with ten times the lethal dose and when at the same time sulfathiazole was introduced into the wound, 97 per cent recovered. Although various other experimenters have not obtained such results, there seems to be good evidence for the use of the sulfonamides locally. However, their effectiveness is probably dependent upon the local flora of bacteria in the infected tissues in addition to anaerobic gas bacteria. There are apt to be streptococci of the aerobic variety which use up the oxygen in the wound, producing an *anaerobic* medium. The local irritating effects of the sulfonamides would not be helpful. Penicillin is far preferable and should be used locally and parenterally in large doses.

Small wounds should be opened widely. Oxygen should be given by inhalation and a sterilized tube may be placed under the dressing which is attached to an oxygen tank, thus supplying the wound with oxygen directly. Wide incisions into the crepitant tissue with the foregoing treatment may save life and the extremity if instituted early. Should signs of septicemia appear or should the infection continue to spread, then amputation must be done promptly. Preliminary treatment with ice for a short period is indicated (q.v.). The amputation is done without flaps; that is, the "chop" or guillotine type is done. The stump is left wide open. Subsequently the stump may be surgically improved or flaps may be formed by stretching the skin with weights, or skin grafts may be used.

2. Phlegmon, or diffuse cellulitis, is also characterized by a toxemia and by wide destruction of tissue. This condition has been discussed in Chapter 4.

3. Hospital gangrene (phagedena or wound diphtheria) is very rare now. It may be due to the streptococcus or to a symbiotic growth of bacteria. Higher diphtheroids closely resembling the Klebs-Loeffler group may cause ulcers of the legs. Diphtheria antitoxin is specific for wound diphtheria—not for the diphtheroid.

Fig. 55.—Gas gangrene of the leg. The upper large granulating area was opened surgically. The lower one is the site of the injury. Gas in the tissues could be felt and was demonstrated by x-ray. The cellulocutaneous type of erysipelas resembles this lesion in the undermining of the skin. The wound was irrigated with hydrogen peroxide, and gas bacillus antitoxin given. The patient recovered.

4. Noma, cancrum oris, or gangrenous stomatitis is due to a mixed infection in the mouth. No doubt the devastating streptococcus is usually the causative organism. Since it occurs in debilitated children after scarlet fever or measles or in the early stages of leucemia, it is probably the "soil rather than the seed" that is at fault. It results in large sloughs of the cheek, with resulting high mortality. Trauma in the mouth by tooth extractions, etc., is contraindicated in such children. A similar condition rarely occurs about the genitals—noma pudendi.

The treatment of gangrenous stomatitis is repeated blood transfusion, adequate food and fluid intake, and sulfonamides, penicillin, and streptomycin. Locally surgery is contraindicated. A mouthwash of normal saline may be used but no strong antiseptics.

5. Ulcers due to specific organisms occur in mycotic infections and in tuberculosis, syphilis, chancroid, etc. *Mycotic infections*, lympho-

Fig. 56.—*A*. Photomicrograph of muscle tissue infected with the Welch bacillus. Note the organisms and the destruction and separation of the muscles. *B*. Cross section of muscles, showing separation by gas.

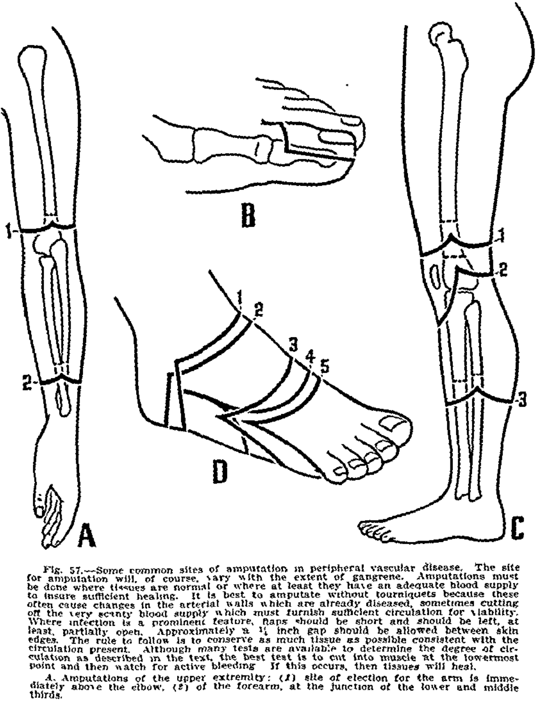

Fig. 57.—Some common sites of amputation in peripheral vascular disease. The site for amputation will, of course, vary with the extent of gangrene. Amputations must be done where tissues are normal or where at least they have an adequate blood supply to insure sufficient healing. It is best to amputate without tourniquets because these often cause changes in the arterial walls which are already diseased, sometimes cutting off the very scanty blood supply which must furnish sufficient circulation for viability. Where infection is a prominent feature, flaps should be short and should be left, at least, partially open. Approximately a ½ inch gap should be allowed between skin edges. The rule to follow is to conserve as much tissue as possible consistent with the circulation present. Although many tests are available to determine the degree of circulation as described in the text, the best test is to cut into muscle at the lowermost point and then watch for active bleeding. If this occurs, then tissues will heal.

A. Amputations of the upper extremity: *(1)* site of election for the arm is immediately above the elbow, *(2)* of the forearm, at the junction of the lower and middle thirds.

B. Lines of incision for amputation of the great toe.

C. Amputations of the lower extremity: *(1)* site of election at junction of lower and middle thirds (about 20 cm below the perineum), or just above the condyles; *(2)* the Gritti-Stokes amputation is slightly below the knee and conserves the patella for weight bearing; *(3)* below the knee amputations are best done at the junction of the upper and middle thirds, about 15 cm below the bend of the knee), and the fibula is divided at a higher level than the tibia.

D. Amputations through the foot: *(1)* Pirogoff; *(2)* Syme, *(3)* Chopart; *(4)* subastragaloid; *(5)* Lisfranc. These amputations will find few indications in peripheral vascular disease. Occasionally, however, they may be used.

Fig. 58.—Noma, cancrum oris, or gangrenous stomatitis.

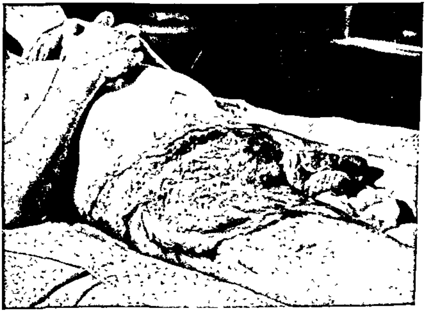

Fig. 59.—Spreading gangrene of the abdominal wall in a debilitated elderly man, following cecostomy.

granuloma inguinale, and granuloma inguinale are discussed in Chapter 7. They are extremely difficult to cure unless they are diagnosed early and excised. *Tuberculous* ulcers heal if and when the infection is arrested. *Syphilitic* ulcers *respond well to mixed treatment.* Exact diagnosis in ulcer of infectious origin may not be possible without the aid of the laboratory (smears, serological test, and biopsy).

6. Symbiotic gangrene is perhaps not an entity since most infections producing gangrene are combinations of organisms. Specifically the term has been used in streptococcus-staphylococcus infections producing widespread destruction of tissue. These are discussed in Chapter 4.

NEUROPATHIC ULCERS

Mal perforant is a painless ulcer on the heel.

Corneal ulcer after removal of the Gasserian ganglion for tic douloureux is neuropathic, as are also the ulcers on the extremities in tabes dorsalis. Does the ulcer develop because of a trophic disturbance to the part or because of anesthesia? This question is difficult to answer. If there is no feeling, repeated injury will remain unrecognized, permitting an ulcer to form. Syringomyelia and tabes dorsalis are diseases which may be complicated by ulcers of this type.

Peptic ulcer has been thought by some to be neuropathic in origin; indeed there seems to be ample ground for this hypothesis (Chapter 20).

MALIGNANT ULCER

As we shall learn in Chapter 15, a sore that does not heal is apt to be carcinomatous. On the lower lip we see squamous-cell carcinoma; on the face, basal-cell carcinoma; and in old, burned areas, Marjolin's ulcer, a form of squamous-cell carcinoma. The diagnosis is not difficult but may be made conclusive by biopsy. The treatment is excision or destruction by radium and x-ray.

ULCERS ASSOCIATED WITH SPLENOMEGALY

Such diseases as sickle-cell anemia, splenic neutropenia, Banti's syndrome, and hemolytic (spherocytic-acholuric) jaundice may be directly related to intractable ulcers of the lower legs. The cause of this mysterious combination is not known. No specific organisms are involved, and all local factors may be normal. After splenectomy the ulcers heal without specific therapy in most instances. (See Chapter 22.)

DISTURBANCES OF FAT METABOLISM

Fat is not altogether connective tissue with fat cells. It is perhaps an organ possessing in part some glandular function (Chapter 16). Local areas of fat necrosis (lipogranuloma) are observed in the breast and abdominal wall as well as in the omentum and other areas. The reaction

induced by mild or severe trauma may resemble carcinoma clinically but not microscopically where a focus of dead fat is seen surrounded by granulation tissue rich in fibroblasts and resembling a sarcoma. The area should be excised. Fat necrosis associated with acute hemorrhagic pancreatitis occurs in the abdomen. Here the death of fat is accompanied by splitting into fatty acid and glycerol. The glycerol combines with calcium to form a soap.

Lipophage granulomas (Darier sarcoid, erythema induratum—Bazin) may be tuberculids or tuberculosis in fat. Treatment is ill-defined and usually ineffective. Rest and attention to the general condition of the patient are usual measures. Penicillin and streptomycin are now being tried.

Relapsing febrile nodular nonsuppurative panniculitis (Weber-Christian's disease) is a skin disease of unknown etiology. Its name is descriptive of the clinical manifestations. Biopsies help establish the diagnosis. Penicillin is helpful; however, natural remissions occur.

Necrobiosis lipoidica diabeticorum is a cutaneous disease occurring on one or both legs. The lesions are flat, red papules with a yellowish corium containing lipoids and swollen collagen fibers. Treatment consists of insulin for the diabetes, a low fat diet, rest, and light x-ray exposure.

COMBINATIONS

Ulcers occur in many diseases without discovered cause and effect. For example, ulcer of the tongue in syphilis is frequently due to carcinoma. Leprosy and neuropathic ulcers are commonly associated. The many other combinations outlined in this chapter, while not all-inclusive, will give the surgeon an idea of the most common causes of peripheral ulcers and gangrene. In every instance the local lesion should be subjected to biopsy and a careful examination of the patient made.

Necrobiosis lipoidica diabeticorum is a cutaneous disease occurring on one or both legs. The lesions are flat, red papules with a yellowish corium containing lipoids and swollen collagen fibers. Treatment consists of insulin for the diabetes, a low fat diet, rest, and light x-ray exposure.

COMBINATIONS

Ulcers occur in many diseases without discovered cause and effect. For example, ulcer of the tongue in syphilis is frequently due to carcinoma. Leprosy and neuropathic ulcers are commonly associated. The many other combinations outlined in this chapter, while not all-inclusive, will give the surgeon an idea of the most common causes of peripheral ulcers and gangrene. In every instance the local lesion should be subjected to biopsy and a careful examination of the patient made.

Chapter 7

MISCELLANEOUS INFECTIONS

Tetanus.—Tetanus is a disease caused by the bacillus of tetanus (*Clostridium tetani*), a rod-shaped, spore-forming bacillus which lives in an anaerobic environment. The spores assume the shape of small carpet tacks and are very resistant. They are found principally in animal excreta and gain entrance into the body through punctured or other wounds which seal themselves off, excluding air. *Clostridium tetani* are found in lacerated wounds, animal bites, and sometimes after operations on gangrenous extremities. A few cases have been reported after "clean" surgery in which the suture material was thought to be the source of the infection. The presence of spores of *Clostridium tetani* in a sterile wound will not cause tetanus, for the organisms multiply in necrotic tissue in the presence of concomitant infection. In this favorable medium the bacilli grow, liberating a water-soluble substance that diffuses through the adjacent skeletal muscles and acts on the neuromuscular end organs to cause a state of maintained contraction. Some of the exotoxin is absorbed by the blood capillaries and lymphatics.

Firor states that the symptoms of tetanus are due to absorption of the toxin by the lymphatics and capillaries. It then affects the motor end plates, initiating tonic but not clonic spasms of the muscles. Life or death depends on the amount of "altered" or lethal toxin in the spinal cord. The convulsions (clonic contractions) of tetanus are of central origin, whereas the rigidity (tonic spasm) of tetanus is entirely due to the action of the toxin on the neuromuscular end organs. Minute quantities of tetanus toxin, introduced directly into the anterior horn cells of the lumbar cord in dogs, produce severe clonic spasms but no rigidity. These animals die without any other evidence of tetanus although the dose is sublethal. Transection of the cord does not prevent the passage of the toxin from the nonvital portion of the spinal cord to the vital centers of the medulla. Division of all distal roots stops convulsive movements in the hindquarters but does not prevent death. Neutralizing doses of antitoxin (1,000 units or more) given intravenously before making spinal injections do not prevent death—even though free antitoxin is circulating in the blood at the time of death. Firor believes as a result of these experiments that tetanus toxin is altered in the cord to form a lethal toxin which is not neutralized by antitoxin, even if a million neutralizing doses are used. Tetanus toxin is not the only example of stepped-up virulence which may occur within the body although this seems paradoxical in view of the body's defense mechanisms. There is some evidence that in diphtheria a toxono is stepped up which affects muscles. An exotoxin can do this but not an endotoxin because the bacteria are taken out by the reticulo-endothelial system. Cross-circulation experiments further substantiate this hypothesis, for the recipient dog dies shortly after the donor dog develops convulsions. Both die of respiratory failure. If antitoxin is used before a lethal quantity of toxin is fixed in the spinal cord, the animal may be saved—even after symptoms of tetanus have developed. Tetanus is, then, a disease involving (1) muscles, affecting those muscles which have the best blood supply

toxoid. Two injections of 1 c.c. of the combined toxoids are given three to four months apart. Very few reactions occur. Then, should exposure occur, a third dose of the tetanus toxoid is administered, protecting the patient in the emergency and perhaps for one to two years. However, another activating dose may be given when needed. Toxoid is made from bacterial toxins plus formalin incubated at 37° for thirty days. This gives rise to a nontoxic antigen or toxoid.

Experiences in the French army have shown the value of tetanus toxoid. Three injections of 1 c.c. each are given at monthly intervals. The U. S. Army circular advises an initial dose of toxoid (1 c.c.) administered subcutaneously on three occasions three to four weeks apart. A stimulating dose of 1 c.c. is given (a) at the end of one year, (b) before going to the theater of war, and (c) on receiving a wound. The British army in some echelons have also given tetanus antitoxin when a soldier is wounded. There is good evidence to show that the antitoxin may inhibit the antigenic action of toxoid for a period of two to four weeks; therefore the advisability of using the antitoxin with toxoid is questionable.

Should the disease occur, the treatment is again a thorough cleaning up of the source of infection after preliminary injection of antitoxin about the wound and then the administration of daily doses of tetanus antitoxin, intravenously, intramuscularly, and subcutaneously. Some observers insist that antitoxin should be given intrathecally through cisternal or lumbar puncture or both. Others aver that it may contribute to a fatal outcome by causing excitement, serum meningitis, and possibly cerebral or medullary edema. Perhaps the preservatives used in antitoxin are the irritating factor. We do not use tetanus antitoxin intrathecally. Concerning the administration of antitoxin, the rule is to give "enough."

The *treatment* of tetanus, according to Frior, consists in (1) injection of tetanus antitoxin (30,000 to 40,000 units) around the wound, to prevent dissemination of the toxin, (2) careful cleansing of the wound and drainage one half hour after the above injection, (3) the injection of an additional 70,000 units of antitoxin intravenously the first day, then daily intravenous injections of 5,000 units (because the antitoxin is rapidly destroyed in the body, eight to ten days), (4) either in oil per rectum to control convulsions, and (5) the use of artificial means of respiration to resuscitate the patient should respiration stop. Barbiturates or morphine should not be used to control convulsions for both are respiratory depressants and in tetanus death is caused by respiratory failure.

For the control of convulsions, ether in oil, given rectally, is best. Recently curare has been suggested in doses of 0.010 Gm. per kilogram intramuscularly. This drug has been used to supplement gas anesthesia because of its relaxing effect. Its use in tetanus is still experimental. The patient should be put into a dark room from which noise is excluded, because external stimulation tends to produce convulsions. If the patient has had serum of any kind before, or if he is the victim of hay fever, asthma, or hives, it is well to give the *antitoxin at half-hour intervals.* In the presence of the disease this same routine is followed before larger doses (5,000 units) are injected at daily intervals. Penicillin and streptomycin

and are used the most (therefore, the masseters) and (2) central nervous system and medullary centers, causing clonic convulsions and death from respiratory failure. (The reason the diaphragm is not affected as early as the masseters is probably that it is not so well supplied with blood.)

It was formerly thought that the toxin ascended in the nerve sheaths or perineural lymphatics until it reached the motor cells of the cord, medulla, and brain. This seemed to explain the clinical observation that the longer the incubation period, the more mild the disease; and the further removed the lesion from the brain, the longer the incubation period and consequently the less severe the infection. It was thought that the early trismus (tetanic spasm of the jaw or masseter muscles) was due to the lower portion of the motor area's being affected first. Firor's explanations seem to disprove these concepts.

He found an insufficient amount of toxin in excised nerves of animals with tetanus to explain the disease and showed that even if the toxin is in the perineural and endoneural lymphatics there is no evidence that they communicate with the cerebrospinal fluid or cord.

Whatever the explanation, because of the early spasm of the muscles of mastication, the jaw is fixed; therefore the popular name lockjaw. Later, other muscles become affected causing generalized tonic and clonic convulsions.

Treatment.—It should be remembered that high fever ensues from toxemia, and, if the patient is not actively treated, death occurs from respiratory failure. The prognosis is not good when there are generalized convulsions because this means that the toxin has entered the spinal cord. The mortality is about 30 per cent after such symptoms have occurred. The *treatment* is chiefly prevention and consists of a thorough and complete cleaning out of wounds, if seen within the first six to eight hours as described in Chapter 16. If seen later than this, and if the possibility of tetanus is strong, then 10,000 units of tetanus antitoxin should be injected about the wound *before* the cleansing process is begun to prevent dissemination of the toxin.

The wound is cleaned an hour or so later by flushing with hydrogen peroxide so that more oxygen may reach it, removing any foreign body that may be present and leaving it open so that the air may have ready access to the field.

This description of the first phase of the treatment of tetanus is a particular application of a fundamental rule in the prevention and treatment of any septicemia or toxemia; namely, "If the acute focus can be eliminated, blood stream infections will not ccur or will usually be annihilated."

Second in importance is the administration of 5,000 units of tetanus antitoxin. This does not prevent the disease but ameliorates its severity. should it occur. Tetanus toxoid is available now which may solve the problem of tetanus. It is given early in childhood along with diptheria

head demand the Pasteur treatment, because one does not dare wait for symptoms in the animal. (5) It is not necessary that obvious wounds be inflicted. Saliva of an infected animal on any small wound or open sore may cause the disease. Therefore, nurses and physicians who come in contact with known rabid animals or patients should take the Pasteur treatment. (6) The immunity conferred by the treatment is said to last approximately six months. (7) There is no evidence that animals may carry *the disease without being infected; however, they are infectious for about* three to five days before symptoms occur. If the virus does not get to the nerves or does so only in minute amounts due to a bite through heavy clothing, the patient may not contract the disease—exclusive of treated cases, only one out of six people exposed to rabies get the disease. Local treatment by cauterizing agents such as nitric acid is advocated by most *authorities provided the wound is seen within a half hour. In experimental* animals 20 per cent soap solution used within thirty minutes protects more animals than nitric acid, tincture of iodine, or sulfanilamide.

Granuloma Inguinale.—Granuloma inguinale is believed to be caused by the so-called *Donovan bodies.* The term granuloma is applied to those infections which are characterized by a great amount of granulation tissue. They are usually chronic and may be nonspecific in origin. It is probably the time element (chronic) rather than any specific tendency of the organism that calls forth the response. The disease is said to be venereal in origin.

Symptoms and Signs.—Chronic progressive ulcerations about the genitals, rarely the face or mouth, with many draining sinuses. Not many general symptoms. The *diagnosis* is made by finding the rodlike *Donovan bodies* in large mononuclear cells from scrapings of the lesions.

Prognosis and Treatment.—The disease runs a chronic course but can be cured. The treatment is increasing daily doses of antimony and potassium tartrate (tartar emetic up to $\frac{1}{10}$ grain). Aureomycin has been used recently with promising results. The dose is 25 mg. per kilogram of body weight every twenty-four hours in five equal doses.

Lymphogranuloma Inguinale (Lymphogranuloma Venereum, Lymphopathia Venereum).—Esthiomene is the name given to the disease with swollen vulva. *The causative agent* is a filtrable virus known as the Frei *antigen. The disease is communicated by personal contact and is usually* venereal in origin.

Symptoms and Signs.—A small sore appears on the genitals and is followed by swollen lymph glands. These soon break down and discharge a white pus. The entire genital region becomes a mass of draining sinuses, with draining fistulas extending into the bladder or rectum. Strictures of the rectum are common. The *diagnosis* is made by biopsy which shows the absence of Donovan bodies and a fairly characteristic microscopic picture. The Frei-Hoffman skin test helps. The disease may resemble chronic ulcerative colitis and may rarely give a positive skin test.

are used to control concomitant infections in the wound and to prevent lung complications. They are especially useful in tetanus from wounds not accessible for débridement and wide open drainage, such as tetanus of the uterus from induced abortion.

Hydrophobia or Rabies.—The disease is caused by a filtrable virus or a toxin which affects the central nervous system. This produces small black areas in the brain called Negri bodies. The disease is transmitted by the saliva of infected animals, principally dogs, but rabbits, chickens, fox, squirrels, and others have been known to transmit the disease. Pathological changes are very meager except for the Negri bodies

Symptoms and Signs.—In the dog there are two types, the dumb and the furious. In the former, the dog is languid and semiparalyzed; he lies lazily around, drooling saliva. The furious is accompanied by irritability, restlessness, and a tendency to snap and bite other animals and people. The incubation period in the dog is three to six weeks or longer. The disease gets its name from the fact that there is a spasm of the laryngeal muscles whenever swallowing is attempted. This makes the animal seem to be afraid of water. The disease is invariably fatal. In man, the incubation period is three to six weeks, sometimes longer. The virus travels along the peripheral nerves; therefore, a bite in the leg would have a longer incubation period than one on the head. The symptoms in man are restlessness, pain in the region of the wound, difficulty in swallowing, and regurgitation of water through the nose when swallowing is attempted and, finally, increasing dyspnea, convulsions, coma, and death. The diagnosis is made by watching the dog. Once symptoms occur in man, the disease is also invariably fatal.

Tetanus causes no demonstrable pathological changes internally. *Rabies* is identified by the presence of Negri bodies and diffuse degenerative changes, with cellular infiltration in the cord, midbrain, medulla, and the basal nuclei.

Treatment.—The treatment consists entirely in prophylaxis because treatment is unavailing after symptoms appear. The following rules should be followed: (1) Whenever a dog bites an individual, the animal must be locked up or confined and observed for two weeks. If at the end of that time no symptoms occur, it is not necessary to give the Pasteur treatment to the patient. (2) If symptoms occur in the dog, he must *not* be killed. He should be sent to the veterinary or kept confined until death. The head should then be sent to the State Board of Health. Pasteur treatment is started as soon as symptoms occur in the animal. This consists of fourteen, or if the animal is known to be infected, twenty-one injections of antirabies virus, made from the spinal cords of infected rabbits. Since the length of such immunity is short, vaccination should be repeated if a second bite occurs later. (3) All stray dogs that bite may be infected; therefore, any person who is bitten by a stray dog that cannot be found should take the Pasteur treatment. (4) Any dogbites about the face or

head demand the Pasteur treatment, because one does not dare wait for symptoms in the animal. (5) It is not necessary that obvious wounds be inflicted. Saliva of an infected animal on any small wound or open sore may cause the disease. Therefore, nurses and physicians who come in contact with known rabid animals or patients should take the Pasteur treatment. (6) The immunity conferred by the treatment is said to last approximately six months. (7) There is no evidence that animals may carry the disease without being infected; however, they are infectious for about three to five days before symptoms occur. If the virus does not get to the nerves or does so only in minute amounts due to a bite through heavy clothing, the patient may not contract the disease—exclusive of treated cases, only one out of six people exposed to rabies get the disease. Local treatment by cauterizing agents such as nitric acid is advocated by most authorities provided the wound is seen within a half hour. In experimental animals 20 per cent soap solution used within thirty minutes protects more animals than nitric acid, tincture of iodine, or sulfanilamide.

Granuloma Inguinale.—Granuloma inguinale is believed to be caused by the so-called *Donovan bodies.* The term granuloma is applied to those *infections which are characterized by a great amount of granulation* tissue. They are usually chronic and may be nonspecific in origin. It is probably the time element (chronic) rather than any specific tendency of the organism that calls forth the response. The disease is said to be venereal in origin.

Symptoms and Signs.—Chronic progressive ulcerations about the genitals, rarely the face or mouth, with many draining sinuses. Not many general symptoms. The *diagnosis* is made by finding the rodlike *Donovan bodies* in large mononuclear cells from scrapings of the lesions.

Prognosis and Treatment.—The disease runs a chronic course but can be cured. The treatment is increasing daily doses of antimony and potassium tartrate (tartar emetic up to $\frac{1}{10}$ grain). Aureomycin has been used recently with promising results. The dose is 25 mg. per kilogram of body weight every twenty-four hours in five equal doses.

Lymphogranuloma Inguinale (Lymphogranuloma Venereum, Lymphopathia Venereum).—Esthiomene is the name given to the disease with swollen vulva. *The causative agent* is a filtrable virus known as the Frei antigen. The disease is communicated by personal contact and is usually venereal in origin.

Symptoms and Signs.—A small sore appears on the genitals and is followed by swollen lymph glands. These soon break down and discharge a white pus. The entire genital region becomes a mass of draining sinuses, with draining fistulas extending into the bladder or rectum. Strictures of the rectum are common. The *diagnosis* is made by biopsy which shows the absence of Donovan bodies and a fairly characteristic microscopic picture. The Frei-Hoffman skin test helps. The disease may resemble chronic ulcerative colitis and may rarely give a positive skin test.

Prognosis and Treatment.—The prognosis is not very good. Years are often required to cure this disease. If seen early, complete excision of the infected glands and dilation of the rectal stricture may be curative. Later, excision of the rectal stricture may be necessary. The latter is accomplished by first doing a colostomy; then the stricture is excised and end-to-end anastomosis is done. (See Chapter 20.) Some advise the intravenous injection of the Frei antigen. Sulfonamides, penicillin, and streptomycin have been used with only fair success and aureomycin with much better results.

Diphtheria.—The *causative agent* is the Klebs-Löffler bacillus or the diphtheria bacillus. The disease is contagious and is caused by contact with the organism.

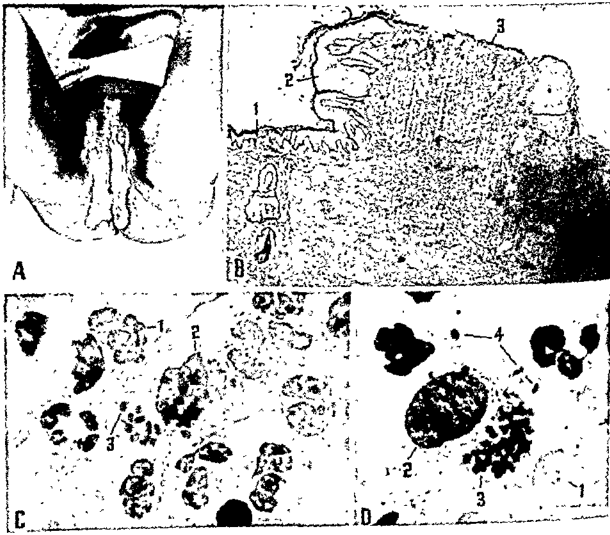

Fig. 60.—Granuloma inguinale. *A*. Clinical photo showing ulceration of vulva. *B*. Fig. 61.—Lymphogranuloma inguinale, showing the enlarged inguinal nodes.

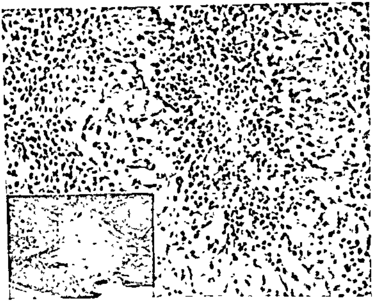

Fig. 62.—Lymphogranuloma inguinale. The low power shows extensive scarring of the lymph glands One of the surrounding lighter areas is seen in the high power. The nodule resembles a tubercle, it is surrounded by epithelioid cells. Its center, however, is filled with cells (lymphocytes and some polymorphonuclears) instead of caseous material. The necrotic material in these nodules is treated with phenol and heated to make the Frei antigen.

Symptoms and Signs.—The most common form is in the throat, where the germ produces a tough grayish pseudomembrane. There are marked general symptoms, with fever and malaise. We are interested here in the form which occurs in wounds, sometimes seen in nurses and physicians, causing a large slough which is covered by a pseudomembrane. Perhaps this was the "hospital gangrene" spoken of in the pre-Listerian days. The diagnosis is made by the clinical appearance and by the identification of the organism in smears and cultures from the wound. Identification is usually not easy.

Prognosis and Treatment.—The prognosis is good if treatment is promptly instituted.

Theoretically the disease should be extremely rare, which indeed it is in the author's experience. This is due to the widespread immunization against the disease (diphtheria toxoid). Should the disease occur, the treatment consists of large doses of diphtheria antitoxin. Local treatment consists of normal salt solution packs.

Yeastlike Fungus Infections.—These include blastomycosis, coccidioidal granuloma, torula infections, and histoplasmosis.

BLASTOMYCOSIS.—Blastomycosis is the chronic infectious disease of the skin, and occasionally of the lungs, caused by the yeastlike fungi *Blastomyces hominis* and *Coccidiodes immitis.* The fungus gains entrance through an injury or superficial wound and causes the development of small papules. Their development is extremely slow and the physician is apt to diagnose them as boils. Soon they break and discharge pus. This results in a widely indurated, bluish, hard area with multiple draining sinuses.

Diagnosis.—The diagnosis is made by finding the yeast fungus in the discharge, or better, in the biopsied tissue, which resembles tuberculous granulation tissue.

Treatment.—This consists of x-ray and the internal use of potassium iodide in increasing doses. The pulmonary form resembles tuberculosis. It is diagnosed by finding the fungus in the sputum. The iodides may help but this form of the disease is usually fatal. If seen early and diagnosed, excision of the lesions may result in cure.

COCCIDIOIDAL GRANULOMA (California Disease).—Coccidioidal granuloma is caused by the *Oidium coccidioides.* It is spherical and resembles the blastomyces but it multiples by the formation of endospores, whereas the blastomyces does so by budding. The disease resembles syphilis or tuberculosis clinically and microscopically. The lungs and other organs show calcification. Two chief varieties are seen: (1) the mild primary acute uncomplicated type called valley fever and (2) the chronic, highly fatal form which may affect any tissue or organ. Cattle, dogs, sheep, and other animals may harbor the fungus. Pus from the lesions may be injected into a male guinea pig; suppurative orchitis develops. There is no specific treatment.

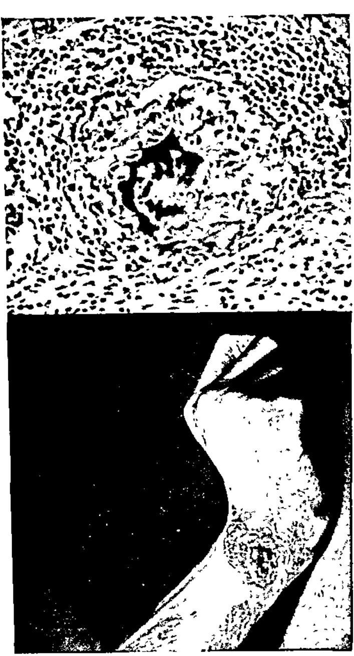

Fig. 63.—Blastomycosis. The chronic ulcerative lesion is shown. The photomicrograph shows the typical tissue reaction and the *Blastomyces*, with its double capsule. There are many fibroblasts, small mononuclears, and macrophage cells and some polymorphonuclears.

Symptoms and Signs.—The most common form is in the throat, where the germ produces a tough grayish pseudomembrane. There are marked general symptoms, with fever and malaise. We are interested here in the form which occurs in wounds, sometimes seen in nurses and physicians, causing a large slough which is covered by a pseudomembrane. Perhaps this was the "hospital gangrene" spoken of in the pre-Listerian days. The diagnosis is made by the clinical appearance and by the identification of the organism in smears and cultures from the wound. Identification is usually not easy.

Prognosis and Treatment.—The prognosis is good if treatment is promptly instituted.

Theoretically the disease should be extremely rare, which indeed it is in the author's experience. This is due to the widespread immunization against the disease (diphtheria toxoid). Should the disease occur, the treatment consists of large doses of diphtheria antitoxin. Local treatment consists of normal salt solution packs.

Yeastlike Fungus Infections.—These include blastomycosis, coccidioidal granuloma, torula infections, and histoplasmosis.

Blastomycosis.—Blastomycosis is the chronic infectious disease of the skin, and occasionally of the lungs, caused by the yeastlike fungi *Blastomyces hominis* and *Coccidiodes immitis*. The fungus gains entrance through an injury or superficial wound and causes the development of small papules. Their development is extremely slow and the physician is apt to diagnose them as boils. Soon they break and discharge pus. This results in a widely indurated, bluish, hard area with multiple draining sinuses.

Diagnosis.—The diagnosis is made by finding the yeast fungus in the discharge, or better, in the biopsied tissue, which resembles tuberculous granulation tissue

Treatment.—This consists of x-ray and the internal use of potassium iodide in increasing doses. The pulmonary form resembles tuberculosis. It is diagnosed by finding the fungus in the sputum. The iodides may help but this form of the disease is usually fatal. If seen early and diagnosed, excision of the lesions may result in cure.

Coccidioidal Granuloma (California Disease).—Coccidioidal granuloma is caused by the *Oidium coccidioides*. It is spherical and resembles the blastomyces but it multiples by the formation of endospores, whereas the blastomyces does so by budding. The disease resembles syphilis or tuberculosis clinically and microscopically. The lungs and other organs show calcification. Two chief varieties are seen: (1) the mild primary acute uncomplicated type called valley fever and (2) the chronic, highly fatal form which may affect any tissue or organ. Cattle, dogs, sheep, and other animals may harbor the fungus. Pus from the lesions may be injected into a male guinea pig; suppurative orchitis develops. There is no specific treatment.

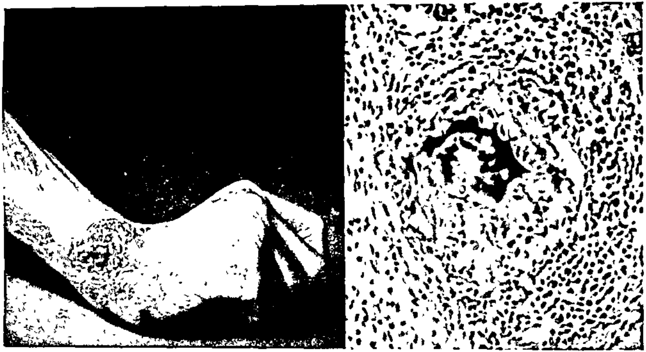

Fig. 63.—*Blastomycosis.* *The chronic ulcerative lesion is shown.* *The photomicrograph shows the typical tissue* reaction and the *Blastomyces,* with its double capsule. There are many fibroblasts, small mononuclears, and macrophage cells and some polymorphonuclears.

TORULA INFECTIONS.—Torula infections are caused by a yeast resembling the blastomyces. It may cause a meningo-encephalitis which is secondary to lung or other lesions.

HISTOPLASMOSIS.—Histoplasmosis (Darling) or reticulo-endothelial cytomycosis is caused by a yeastlike body, the *Histoplasma capsulatum.* The parasites occur in phagocytic cells as well as fixed reticulo-endothelial cells of the liver and spleen. They may be found in lymph nodes, bone

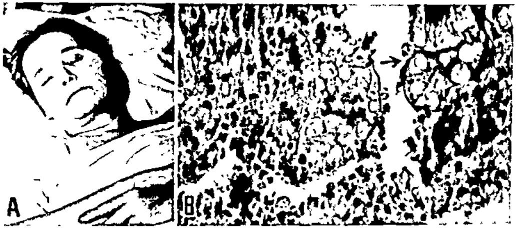

Fig. 64.—*A*. Clinical photograph of a patient with torulosis, showing swelling in parotid region. *B*. Abscess showing organisms in giant cells. Hematoxylin and eosin stain. The arrow points to a typical giant cell with organism

marrow, and the peripheral blood. Clinically the disease may resemble kala-azar with fever, enlarged liver and spleen and lymph nodes, anemia, and leucopenia. There is great weakness and loss of weight. We have seen the disease in a child 3 years of age and in a man 70 years old. Biopsy of the lymph nodes or sternal puncture may reveal the organisms. It has been found in the stools. There is no satisfactory treatment for this

fatal disease. Recent studies have shown that the disease may appear in a mild form and that it is probably very common in many river valleys. Clinically the mild form of the disease resembles tuberculosis. The lungs and other organs show extensive calcification. Histoplasmin is used as a skin test and is interpreted much as the tuberculin test in making a diagnosis, although its reliability is questionable.

Actinomycosis.—Actinomycosis is another example of a fungus disease. It is caused by the *Actinomyces bovis* or ray fungus, a streptothrix which is a large, round organism with small bulblike threads extending around the periphery. As the fungus grows, it causes a slow but active *inflammation, with the formation of a large amount of granulation tissue,* particularly rich in macrophages, monocytes, and fibroblasts. (All diseases having this effect are called granulomas—tuberculosis, syphilis, and fungus infections). Soon secondary invaders enter the area and frank suppura*tion occurs. In the pus are small yellow grains called "sulfur granules."* The Actinomyces may be found in them or they may be composed of mycelia and parts of the organism. The infection ultimately produces extensive infiltration, which is seen clinically as a hard indurated area with *many draining sinuses, although the lymph glands are not involved.* In cattle the disease is called *lumpy jaw* because of the hard "lumps" that occur in the neck. It is said to occur in them from eating grains or grasses contaminated by the fungus. A slight abrasion in the mouth affords easy access. *In man two forms are seen: local and internal. The former* is usually in the head and in the neck and rarely in the skin elsewhere; the latter in the lungs, appendix, Fallopian tubes, and intestines, although any organ may be involved. The disease does not spread by the lymphatics *and therefore the lymph nodes are uninvolved. In this way it may* be distinguished from syphilis and tuberculosis. The spread is from the subcutaneous and submucous tissue by direct continuity. If a blood vessel is involved, the organism may be carried to any organ.

Diagnosis.—The diagnosis is made from the clinical signs (chronic inflammation with induration of tissues, very little pain and fever, absence of glandular involvement) and the laboratory tests. The internal forms show grossly a firm purulent mass of tissue which may resemble carcinoma. In the lungs multiple abscesses may occur. In the ileocecal region the picture may be that of a terminal ileitis. If some of the pus is put into a test tube of normal saline or weak sodium hydroxide, the sulfur granules may be seen. The final diagnosis is made by biopsy and identification of the fungus in tissue sections. Sometimes these organisms (probably benign types of Actinomyces) are found in the mouth or intestinal tract without symptoms. The outlook for the cutaneous form is reasonably good; that for the internal varieties, poor. On the face other lesions resembling Actinomyces must be thought of. The early lesion is usually thought to be a boil or carbuncle. Infected sebaceous cyst, osteomyelitis of the mandible with draining sinuses, anthrax, oriental sore (delhi boil),

Fig. 66.—Actinomycosis of the face in a boy aged 6 years. Great improvement resulted from x-ray treatment and the use of thymol internally.

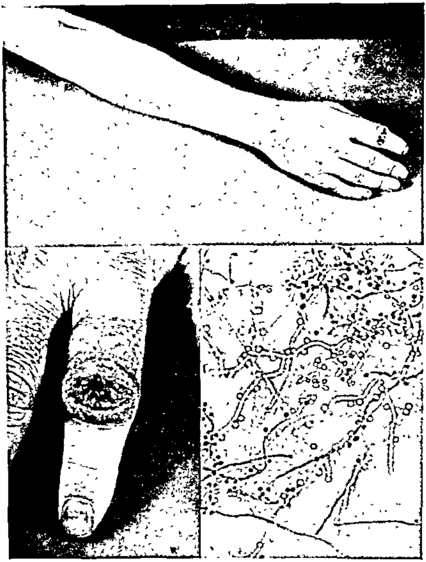
carcinoma, and, in one case, an accidental smallpox vaccination have all been thought to be Actinomyces.

Treatment.—The treatment consists of x-ray and increasing doses of sodium or potassium iodide, large doses of the sulfonamides and penicillin locally (5,000 units per cubic centimeter) as well as intramuscularly,

A.



B. C.

100,000 units every three hours. If the skin lesion is seen early, diagnosed, and excised, a complete cure may be effectuated. In the abdominal varieties, operation, with removal of the diseased organ if feasible, is perhaps the treatment of choice. Ordinarily the surgeon does not make the correct

Fig. 66.—Actinomycosis of the face in a boy aged 6 years. Great improvement resulted from x-ray treatment and the use of thymol internally.

giant cells. There is much necrosis. The disease is prevented by eating only cooked pork. There is no specific treatment. A skin test is available for diagnosis.

Staphylococcic Actinophytosis (Botryomycosis).—A mass of granulation tissue in a wound is ordinarily seen after healing by second intention. If it is removed and recurs, it may resemble carcinoma or fungus infection. *Pyogenic* granuloma is an excessive formation of granulation tissue caused by the staphylococcus. It has been called botryomyocosis or mycetoma because of its resemblance to such lesions in horses. The lesion contains granules which resemble the "sulphur granules" of actinomycosis. When crushed and stained with Gram stain, they are found to contain staphylococci. It is best treated by excision followed by x-ray.

Amebic Dysentery.—This is caused by the *Entamoeba histolytica*, a motile protozoon similar to the ameba we see in stagnant water. It is taken into the body in infected food or drink. It is extremely common in tropical countries, where carriers transmit the disease without themselves having symptoms. The amebae produce widespread ulceration in the colon and, rarely, in the small intestine. They do this by penetrating the lumen of the glands and reaching the submucosa where they produce necrosis by a proteolytic ferment which they release. The mucosa over the necrotic area dies, causing sloughs with large ragged undermined edges. In addition, the portal capillaries occasionally carry the amebae to the liver, where an *amebic* abscess may develop. This is usually a large single abscess with ragged necrotic walls and a great destruction of tissue. The chief symptom of amebic dysentery is a persistent diarrhea, with mucus and blood in the watery or loose stools. There may be fifty or sixty stools a day, and sometimes enormous sloughs of the mucus membrane occur. Occasionally diarrhea is not a prominent feature and the first evidence of the disease is a pelvic, subphrenic, or liver abscess. The patient soon becomes weak, emaciated, dehydrated, and feeble. Death may occur within one to two weeks. The chronic type is much milder but the symptoms are the same. Should a liver abscess occur, there will be chills, fever, sweats, tenderness over the liver, and perhaps a subphrenic abscess as well.

Diagnosis.—The diagnosis depends upon the appearance of the local lesion as seen through the proctoscope and the presence of the organism in the stool. This may be obtained by warm normal salt enema, cathartic, or direct smear. The stool should be placed in a sealed jar and kept warm for the laboratory examination. The physician in making the differential diagnosis must think of other lesions causing diarrhea, such as:

1. Acute infectious diseases: (a) bacilliary dysentery, (b) typhoid fever, (c) paratyphoid, (d) cholera, and (e) trichinosis.
2. Acute noninfectious diseases: (a) poisonings (bichloride of mercury, arsenic and (b) uremia.
3. Chronic infectious lesions: (a) tuberculosis, (b) chronic ulcerative colitis, (c) regional enteritis, (d) lymphopathia venereum, and (e) syphilis.

diagnosis until smears have been made from the abscess which is usually found. Fistulae are apt to follow any abdominal surgical procedure in the presence of Actinomycosis (see Chapter 20).

Granulomatous Nocardiosis.—Granulomatous nocardiosis is a new fungus disease which is thought to be caused by an acid-fast organism of the family of Actinomycetacae, *Nocardia intracellularis* (Cuttino and McCabe). It is a granulomatous inflammation causing proliferation of reticulo-endothelial cells.

Sporotrichosis.—Sporotrichosis is caused by the *Sporothrix schenki*, which grows readily, forming many mycelian threads. It usually occurs on the hands and forearms, with formation of nodules and ulcers along the tubular lymphatics. The lymph nodes are not involved. The disease may be chronic and is treated by palliation locally and increasing doses of iodides. If the iodides are given early there is rapid regression of the disease. If seen very early, local excision is indicated. Diagnosis is made by finding the organism in smears, by culture on Sabouraud's medium, and by intradermal tests.

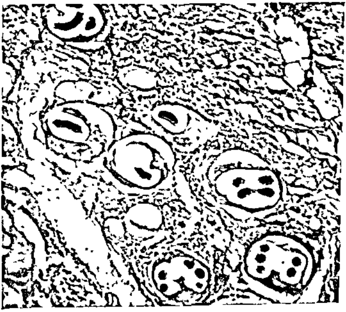

FIG. 69.—Trichinosis. Photomicrograph showing trichinae. Biopsy of skeletal muscle. The patient was a woman aged 21 years who complained of aching over the entire body and pain on motion of extremities. Her temperature was 103° F. and she was greatly emaciated. She had eaten raw pork two months before symptoms began.

Trichinosis.—Trichinosis is fairly common. It manifests itself by generalized muscular pain and tenderness over localized muscle areas. It is caused by the *Trichina spiralis*, a small parasite which walls itself in a capsule in the depth of the affected muscle. It is ingested by eating uncooked pork and is carried by the blood stream to any or all muscles but not to the brain or other organs. In the early stages the cysts are largely made of fat; later they become calcified. These parasites set up a marked inflammatory reaction, with lymphocytes, plasma cells, and foreign body

Anthrax.—Anthrax is an infectious disease caused by *Bacillus antracis*, a large gram-positive bacillus which gains entrance through an abrasion. It forms a pustular lesion, with great swelling and edema, which is accompanied by marked general symptoms. It is known as "malignant pustule" and is usually transmitted by unsterilized shaving or other brushes. It is seen in people handling wool, hides, or animal fur and is common in sheep and cattle. Three days after inoculation a red papule forms which develops into a large lesion with a necrotic center. Fatal pulmonary and intestinal types occur.

Diagnosis.—Diagnosis is made by finding the organism in smears.

Treatment.—The treatment consists of penicillin packs 5,000 units per cubic centimeter locally or bacitracin ointment and penicillin intramuscularly, 100,000 units every three hours.

Fig. 70.—Tularemia. The initial lesion is shown. The infection occurred after cleaning rabbits. The epitrochlear and axillary glands were enlarged. There was great systemic reaction, with chills and fever.

Glanders.—Glanders is also known as farcy. "Buds" and "pipes" appear, signifying involvement of the lymphatics. The disease is caused by *Bacillus mallei* and manifests itself as a rule by chronic indurated ulcers about the air passages Man has no immunity to it. There is a highly fatal pulmonary form. Diagnosis is by smears and discovery of the organism. Treatment is palliative. Vaccine (mallein) has been suggested. Streptomycin is effective.

Mycetoma Pedis (Madura Foot).—Mycetoma pedis is a chronic disease appearing usually in the lower leg and foot. Although the *Actinomyces streptothrix* is said to be the causative organism, the process is prob-

4. Chronic noninfectious lesions: (a) carcinoma, (b) strictures due to any causes such as just mentioned (tuberculosis, syphilis, lymphopathia venereum, regional enteritis, diverticulitis, carcinoma, trauma (such as injection of hemorrhoids followed by sloughs), (c) avitaminosis or deficiency diseases (pellagra sprue), (d) allergy, and (e) neuropathic causes.

5. Miscellaneous causes: pernicious anemia, hyperthyroidism, congestive heart failure, cirrhosis of the liver, leucemia, achylia gastrica, pancreatic disease, Addison's disease, and gastrocolic fistula after gastroenterectomy.

Treatment.—The treatment is by use of ipecac derivatives, such as emetine hydrochloride (0.065 Gm. doses), arsenicals, such as carbarsone (0.25 Gm. tablets) and acetarsone and Diodoquin (5, 7 diiodo-8-hydroxyquinoline) in 210 mg. doses. In chronic colitis, if a specific organism is not found, emetine as a therapeutic is indicated. Amebic abscess of the liver is best treated by emetine, carbasone, and aspiration. The abscess is usually sterile, for the organisms are in its wall and not in the reddish pus. Emetine may be injected into the cavity. Aspiration may be repeated at intervals. If secondary infection is present drainage may be necessary, but due to the high mortality of this procedure even here repeated aspiration should be tried first.

Tularemia.—Tularemia is an infection caused by the *Bacterium tularense* Pasteurella tularensis (after Tulare County, California). It is common in wild rabbits and is transmitted through slight skin abrasions to men who handle wild rabbits. It has come to be known as "rabbit fever" by the laity. The organism grows and produces an inflammation at the site of entrance. This is known as the initial lesion. From here it spreads along the tubular lymphatics, producing a lymphangitis with multiple small abscesses along its path (similar to those seen in sporotrichosis, a fungus infection) and lymphadenitis. There is also a pulmonary form with symptoms resembling pneumonia.

Diagnosis.—The diagnosis is made from a history of handling wild rabbits while hunting or preparing them; also by skin and specific agglutination tests. Agglutinations in dilutions of 1/100 are significant. They remain positive for life due to some continued activity at the site of the lesion.

Treatment.—The disease may be prevented if those who handle rabbits will wear rubber gloves. Other animals (squirrels) have been known to transmit the malady. After the infection is present, treatment is symptomatic, but specific Foshay serum may be tried. The disease is extremely slow in its evolution and cure but it is not often fatal. (The mortality is less than 4 per cent). Repeated blood transfusions are of great value. Streptomycin and Chloromycetin have been used with success.

Four types of tularemia are seen: (1) *Ulceroglandular* (primary lesion and ulceration along lymphatics), (2) *oculoglandular* (primary lesion in the conjunctiva), (3) *glandular* (no local lesion but involvement of the lymph glands), (4), *typhoid type* (resembling typhoid fever).

is no specific treatment. Penicillin and Chloromycetin may be tried. Amputation may be necessary.

Leishmaniasis.—Visceral leishmaniasis, kala-azar, infantile kala-azar, and "death fever" are produced by *Leishmania donovani.* The organism belongs to the protozoa and is usually found in monocytes, reticulo-endothelial cells, and polymorphonuclears. It is round or oval and has an eccentric nucleus and another rodlike chromatin body. Within Wright's stain the protoplasm is light blue with pink nucleus and violet rodlike body. The principal lesions are observed in the spleen (tropical splenomegaly), liver, bone marrow, heart, kidneys, and lymph nodes. The entire reticuloendothelial system, including the free histiocytes, becomes parasitized, producing anemia, leucoplenia, splenomegaly, and enlargement of lymph nodes. The symptoms are chills, fever of an irregular type, edema of the skin with ulcers and hemorrhages, diarrhea, and extreme emaciation. There is no ascites as in intestinal schistosomiasis.

Diagnosis.—The diagnosis is established by finding the *Leishmania donovani* in smears from the peripheral blood, splenic pulp, lymph nodes, or bone marrow.

Treatment.—Treatment is usually with sodium or potassium antimony tartrate. A 2 per cent solution is freshly prepared and in the adult 2 to 5 c.c. are given intravenously every other day until 4 Gm. of the salt have been given. A newer drug is sodium antimony biscatechol disulphonate (Fuadin).

CUTANEOUS LEISHMANIASIS (ORIENTAL SORE, ALEPPO BUTTON, JERICK'S BOIL, DELHI BOIL).—Cutaneous leishmaniasis is caused by *Leishmania tropica.* It is transmitted by the sand fly, *Phlebotomus papatasii.* The disease is characterized by a red papule which later ulcerates. The lesions may occur on the face (most common), lips, hands, or feet. Treatment consists of intramuscular injections of Fuadin, 0.5 c.c. for children and up to 5 c.c. for adults.

MUCOCUTANEOUS LEISHMANIASIS (ESPUNDIA, AMERICAN LEISHMANIASIS).—Mucocutaneous leishmaniasis is caused by *Leishmania braziliensis.* It begins with a sore on an exposed surface of the skin. Later the mucous membrane of the mouth, palate, pharynx and larynx become ulcerated. Treatment is the same in other forms of leishmaniasis.

Schistosomiasis.—This group is caused by digenetic trematodes known as blood flukes or human schistosomes. The organisms lay eggs in veins which are discharged in urine or feces. Eggs hatch in water, forming embryos which hatch and escape as free-swimming organisms. In coming in contact with the fresh water snail they infect it, multiply, and form cercariae which break out of the snail and burrow through the skin of human beings who are swimming or wading. The cycle is then repeated.

VESICAL SCHISTOSOMIASIS (SCHISTOSOMIASIS HEMATOBIA, VESICAL BLOOD FLUKE, SCHISTOSOMA HEMATOBIUM).—There are general *symptoms* of in-

ably conditioned by the growth of various fungi called mycetoma grains. Usually a nodule appears on the plantar surface of the foot. This is followed by others which finally become soft and break, causing multiple sinuses. There may be great destruction of the entire foot involving bones and joints. The clinical appearance resembles tuberculosis. Diagnosis is established by finding the fungus in the infected epidermis or in the pus. There

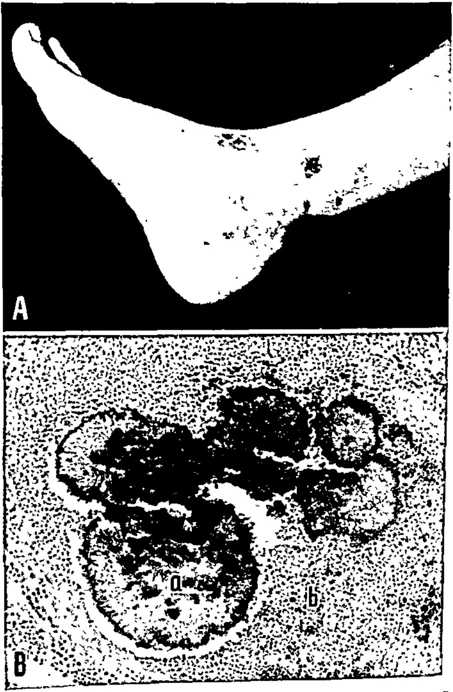

Fig. 71.—*A*, Clinical photograph showing madura foot with many sinuses. *B*, Colony of medura myces in an abscess of the foot (Graham-Weigert stain). *a*, Colony of spores; *b*, pus.

is no specific treatment. Penicillin and Chloromycetin may be tried. Amputation may be necessary.

Leishmaniasis.—Visceral leishmaniasis, kala-azar, infantile kala-azar, and "death fever" are produced by *Leishmania donovani.* The organism belongs to the protozoa and is usually found in monocytes, reticulo-endothelial cells, and polymorphonuclears. It is round or oval and has an eccentric nucleus and another rodlike chromatin body. Within Wright's stain the protoplasm is light blue with pink nucleus and violet rodlike body. The principal lesions are observed in the spleen (tropical splenomegaly), liver, bone marrow, heart, kidneys, and lymph nodes. The entire reticuloendothelial system, including the free histiocytes, becomes parasitized, producing anemia, leucoplenia, splenomegaly, and enlargement of lymph nodes. The symptoms are chills, fever of an irregular type, edema of the skin with ulcers and hemorrhages, diarrhea, and extreme emaciation. There is no ascites as in intestinal schistosomiasis.

Diagnosis.—The diagnosis is established by finding the *Leishmania donovani* in smears from the peripheral blood, splenic pulp, lymph nodes, or bone marrow.

Treatment.—Treatment is usually with sodium or potassium antimony tartrate. A 2 per cent solution is freshly prepared and in the adult 2 to 5 c.c. are given intravenously every other day until 4 Gm. of the salt have been given. A newer drug is sodium antimony biscatechol disulphonate (Fuadin).

Cutaneous Leishmaniasis (Oriental Sore, Aleppo Button, Jerick's Boil, Delhi Boil).—Cutaneous leishmaniasis is caused by *Leishmania tropica.* It is transmitted by the sand fly, *Phlebotomus papatasii.* The disease is characterized by a red papule which later ulcerates. The lesions may occur on the face (most common), lips, hands, or feet. Treatment consists of intramuscular injections of Fuadin, 0.5 c.c. for children and up to 5 c.c. for adults.

Mucocutaneous Leishmaniasis (Espundia, American Leishmaniasis).—Mucocutaneous leishmaniasis is caused by *Leishmania braziliensis.* It begins with a sore on an exposed surface of the skin. Later the mucous membrane of the mouth, palate, pharynx and larynx become ulcerated. Treatment is the same in other forms of leishmaniasis.

Schistosomiasis.—This group is caused by digenetic trematodes known as blood flukes or human schistosomes. The organisms lay eggs in veins which are discharged in urine or feces. Eggs hatch in water, forming embryos which hatch and escape as free-swimming organisms. In coming in contact with the fresh water snail they infect it, multiply, and form cercariae which break out of the snail and burrow through the skin of human beings who are swimming or wading. The cycle is then repeated.

Vesical Schistosomiasis (Schistosomiasis Hematobia, Vesical Blood Fluke, Schistosoma Hematobium).—There are general *symptoms* of in-

fection and local bladder irritation. The diagnosis is established by recovering the organism. Treatment is with tartar emetic potassium antimony tartrate.

INTESTINAL SCHISTOSOMIASIS, SCHISTOSOMA MANSONI.—Intestinal Schistosomiasis is caused by *Schistosoma mansoni*. The symptoms are chiefly diarrhea with general malaise and fever. Later dysentery becomes less prominent but there are loose stools due to fibrous constrictions in the thickened bowel, anal fissures, and fistulae ovum. There may be pronounced splenomegaly or (Egyptian splenomegaly) hepatomegalia. The diagnosis rests upon finding the eggs of the organism. Treatment is with tartar emetic.

ORIENTAL SCHISTOSOMIASIS, SCHISTOSOMA JAPONICUM.—Oriental schistosomiasis is caused by the oriental blood fluke which also causes dysentery and splenohepatomegalia. The treatment is the same as for other types of schistosomiasis.

Echinococcus Disease.—Echinococcus disease or hydatid disease is caused by *Echinococcus granulosus, Echinococcus tenia,* or *Echinococcus multilocularis.* It is a tiny tapeworm which lives in the small bowel of the dog and other hosts. After excretion it may be ingested by intermediary hosts—sheep, hogs, cattle, or man. After the embryo is set loose it burrows out of the intestine and finally settles into the liver, lung, pleura, kidney, brain, and other organs. Here it forms cysts, daughter cysts, brood capsules, and scoleces.

Diagnosis.—The disease is considered as a possibility when cysts or cyst-like swellings are found by physical examination or x-ray study of organs in which symptoms occur. Aids to diagnosis are x-ray examination, the presence of eosinophilia of the organ or the portion involved, precipitin complement fixation, and intradermal tests.

Treatment.—Treatment consists of surgical excision if possible such as lobectomy in the lower lobe of the lung. If not, the cyst may be aspirated, care being taken not to spill any of its contents, thereby preventing secondary contamination and infection. Then 10 to 50 c.c. of 10 per cent formalin is injected and withdrawn after five minutes. Now the cyst is separated from its adventitia and removed. The adventitia is then swabbed with 10 per cent formalin, leaving a small amount. The cavity is then obliterated by suture and the wound closed without drainage. Marsupialization may also be used in conjunction with formalin treatment if secondary infection is present.

SUMMARY

In this chapter we have discussed some of the more common types of miscellaneous infections. There are many more which the surgeon sees, such as bacillary dysentery, Malta or undulant fever, bubonic plague, leprosy, mycosis; protozoan infections such as malaria, relapsing fever;

diseases caused by metazoan parasites, among which are filariasis; and lastly, diseases of partially known etiology, such as infectious jaundice, psittacosis, Rocky Mountain spotted fever or tick fever (caused by rickettsiae), ratbite fever, etc., diseases which are now treated with aureomycin or chloromycetin.

Diagnosis in these diseases is made by clinical observation and by routine and special laboratory tests.

Special laboratory tests are agglutination tests for Malta fever and tularemia, a special agglutination test (heterophile antigen, Paul-Bunnel) for infectious mononucleosis, agglutination with Proteus X19 for typhus (Weil-Felix reaction), search for spirochetes in the urine, and guinea pig inoculation in Weil's disease (spirochetosis icterohaemorrhagica), blood cultures in typhoid, etc.

Certain diseases have similar manifestations and must be ruled out. For example, a group of chronic drainage sinuses are seen in (1) infected wounds with foreign bodies, (2) tuberculosis, (3) syphilis, (4) fungus infections, and in (5) carcinoma or sarcoma. Another example is the group causing an enlarged spleen (splenomegaly), as in kala azar now treated successfully by ethylstibamine Neostibosan) malaria, and Echinococcus infestations. Sometimes the lead is very flimsy; perhaps the patient reveals a bit of important history which he considers irrelevant: a small transient rash, a vacation in another district where certain infections are prevalent, a slight nosebleed, a purpuric spot, a pain in the region of the spleen, etc.

Since the advent of World War II many diseases hitherto considered curiosities may become not uncommon.

Chapter 8
TUBERCULOSIS

Tuberculosis (from tuberculum, a nodule is an infectious and contagious disease caused by the *Mycobacterium tuberculosis.* It is transmitted to susceptible individuals by contact with the germ, either by inhalation (human strain) or by ingestion (bovine strain, usually) and may affect any tissue or organ in the body. Although not primarily a surgical disease, the surgeon is frequently called upon to aid in its management. We should speak of the infection in tuberculosis as a *tuberculous,* not a *tubercular,* infection, for "tubercular" nodules occur in other diseases, such as fungus infections, leprosy, etc.

PATHOLOGICAL FEATURES

The "unit" of the disease is the *tubercle,* which forms when tubercle bacilli are carried to the tissues by the lymphatics, the blood stream, or even by macrophage cells.

Tubercle bacilli may be present in the mucous membrane of the throat, for example. Here the polymorphonuclear cells may ingest them as they would any foreign body. These cells are then carried by the lymphatics to the lymph nodes, where they are fixed. If the polymorphonuclears are injured, the macrophage engulfs both cell and bacteria. If not, bacteria proliferate and destroy the polymorphonuclear cell. In either event, the macrophages engulf them. Growth may also take place inside the macrophage cells. As soon as the bacteria proliferate, tissue cells are injured and a reaction takes place with slight hyperemia, exudation, and attraction of macrophages, epithelioid cells, and giant cells. Some believe this reaction is the same in primary and in secondary infection, except that in the former it is milder. Most observers agree that when the tubercle bacilli first enter the body and find lodgement in the tissues there is no allergy present. Therefore, there is no specific reaction on the part of the tissue. The focus of bacilli is challenged, as any other foreign body or nonspecific infection would be. The walling off process through cellular proliferation is almost complete before allergy can be detected. This reaction holds the tubercle bacilli in check quickly and completely in most cases. It is not due to natural or acquired immunity any more than the reaction to the staphylococcus when it is first met. The most susceptible (Negro, Mexican, Indian) meet it in the same way. After the initial infection, if the tubercle bacilli subsequently reach the tissues either from exogenous or endogenous sources, a specific reaction takes place due to allergy to the tuberculoprotein. Some suggest desensitization as a means of control. Thus we may conclude that (1) allergy in this disease can be produced only by infection with (living or dead) tubercle bacilli and (2) allergy accentuates and hastens the native tissue reactions against tubercle bacilli.

The reaction which is set up by the tissues is specific and more or less typical, especially if the patient has had previous experience with the disease. Whereas it may be difficult to distinguish the *primary infection*

from a nonspecific inflammation (tubercles are rare), yet this initial experience produces a sensitiveness (allergy) to the endotoxin which causes a second infection to form lesions of the *secondary or adult type* which are fairly characteristic of the disease.

In the so-called childhood type in the lungs, for example, the infection is usually in the base of the lung. There may be extensive involvement with perhaps only one (Ghon) tubercle. Some have explained the occurrence of the adult type in infants by endogenous sensitization through the mother.

From the tubercle the disease is spread by continuity of tissue by the blood stream, by the lymphatics, and by phagocytic cells to any and all parts of the body. The tubercle is formed as a result of the endotoxin in the tissues. It is nature's answer to the attack. At first there is a slow, "cold" necrosis, or formation of a cheesy mass, a process known as *caseation or homogeneous coagulation necrosis.*

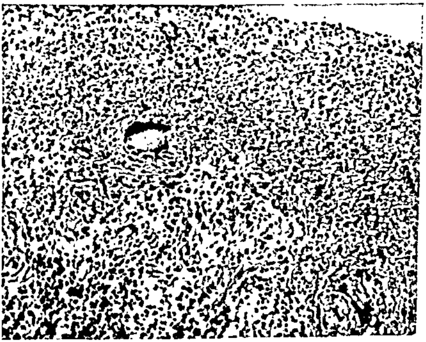

Fig. 72.—Tuberculous granulation tissue. Note the Langhans' type of giant cell and the epithelioid cells surrounding it.

Some pathologists regard caseation as the end result of coagulation necrosis, in which some cells are still recognizable.

Certain cells are now attracted to the area and they arrange themselves in a rather typical manner. There is a central giant cell (Langhans' type) which is surrounded by the the caseous material. This in turn is surrounded by a special type of reticulo-endothelial cell known as an *epitheloid cell,* in palisade arrangement. These cells are important in the histological diagnosis of the disease even if caseation is not present. They come from wandering cells (macrophages) and may form fibroblasts which give rise ultimately to fibrous tissue. Many mononuclear leucocytes are

seen surrounding the area, and there is marked proliferation of fibrous tissue (from fibroblasts). The blood supply to a tuberculous nodule is very poor. Even the capillaries which were present at the onset are obliterated. Therefore, tuberculosis is comparable in its pathological appearance to an infarct. From this "unit" the disease may spread to contiguous tissues. The epithelioid cells, the mononuclears, and the delicate connective tissue undergo the same coagulation necrosis, which in turn produces a similar reaction. In this way many tubercles are joined together (conglomerate tubercle). Finally large areas may be involved and there may be erosion into a large vessel, causing hemorrhage. No tissue is immune to this destructive process.

The *method of spreading* is by (1) contiguity, (2) erosion, (3) erosion into a blood vessel with dissemination, (4) lymphatic invasion, and (5) normal channels, as by coughing up the infected sputum from the lungs and swallowing it, with resultant infection of the gastrointestinal tract.

TERMINATION

Perhaps a better understanding can be obtained of the various types of tissue reaction to the disease by comparing it with nonspecific infections, as is done in the accompanying outline. As was pointed out in Chapter 4, these reactions may vary in type and intensity, depending on the virulence of the organism and the resistance of the patient.

TABLE VII

NONSPECIFIC INFECTION	TUBERCULOUS INFECTION
Resolution	Resolution may and frequently does take place in the adult type and practically always does in the primary type
Necrosis with absorption	Coagulation necrosis (caseation): a small area may be absorbed
Necrosis and sloughing	Cavitation from coagulation necrosis and sloughing
Suppuration (hot)	Liquefaction (cold abscess)
Healing occurs by cicatrization	Fibrosis
	Calcification produces a permanent arrest of infection; while not pathognomonic of tuberculosis, it is most commonly seen as the end stage in this disease

Clinically three types of tuberculosis are usually designated: (1) Exudative—little or no fibrous tissue proliferation occurs and the disease frequently ends in resolution; (2) caseous or ulcerative—caseation occurs with destruction of tissue and cavitation; (3) fibrous, proliferative, or productive (that is, productive of fibrous tissue). One or all of these types may be present in the same organ or tissue.

METHODS OF DIAGNOSIS

A diagnosis of tuberculosis may be made in any of the following ways.

History.—There may be a history of intimate contact with the disease.

Clinical Signs and Symptoms.—There may be slight fever, loss of weight and appetite, and local symptoms and signs; if the lungs are involved, there may be cough, sputum, hemoptysis, etc.

Skin Tests.—Of these, the von Pirquet and Mantoux tests are the best. In the von Pirquet test old tuberculin is used on a skin scratch: an inflammatory reaction indicates a positive test. In the Mantoux test an intracutaneous injection is made: this will cause a skin reaction if positive. A positive test indicates that the individual is allergic to the endotoxin of the tubercle bacillus: as interpreted clinically, this means that the patient has or has had the primary infection. (An anergic reaction is one in which there is a delay in the appearance of allergy). These tests have been found to be positive in 10 to 30 per cent of all adults, with variations in different localities. Therefore, a positive test does not help much in the diagnosis, but a negative test means that the patient does not have tuberculosis (or else that the disease is overwhelming, or that it is obsolete because of complete calcification). In other words, live bacteria must be present and they must have access to the blood stream for the test to be positive. Complete calcification gives a negative test.

X-ray Examination.—X-ray pictures of the affected part will show characteristic lesions. Calcifications may be due to other causes (coccidioidal infections, histoplasmosis) than tuberculous.

Laboratory Tests.—(1) The sputum is examined for acid-fast bacilli —small rod-shaped organisms which stain with difficulty but which, when stained by a special technique, retain the stain even after treatment with acid. (2) A biopsy of the tissue is performed when possible and when positive reveals typical tuberculous granulation tissue, in which the tubercle bacillus may often be seen. (3) A susceptible animal (guinea pig) is inoculated with the sputum or exudate from doubtful cases and in the presence of the tubercle bacillus will develop unmistakable tuberculous lesions.

PROGNOSIS

The prognosis is good. There is no disease which tends to cure itself more readily than tuberculosis. Recovery is slow and involves care, but the infection will in most cases become arrested if the forces of nature are given a chance. Arrest is brought about by fibrosis, or perhaps, more permanently, by calcification. *The general treatment* consists of adequate rest, good food, and sunshine. Streptomycin is extremely useful in many forms of tuberculosis. Other drugs which may help are para-aminosalicylic acid (P.A.S.) and sulfonamides. The local treatment consists of excision or immobilization of the part affected. Rest is secured by conservative measures in children and by more radical measures in adults.

SPECIAL TYPES OF TUBERCULOSIS

Tuberculous Lymphadenitis

Tuberculous lymphadenitis may arise from infection in the blood stream or from a neighboring focus. In the former there may be generalized

involvement of all nodes. Usually the disease is limited to one group which are infected secondarily by the primary focus—the cervical nodes from the tonsils and adenoids, the tracheobronchial nodes from the air passages and lungs, the axillary from the breast or arm, the inguinal from the anus, rectum, and perineum, and the mesenteric from the lymphoid tissue of the ileum, cecum, or appendix. Often the primary site has healed or at least cannot be demonstrated. The cervical glands are most commonly involved. They soon break down and become matted together into a conglomerate mass which may undergo liquefaction. Sometimes a single fibrous node is seen, especially in elderly patients. The treatment is the general treatment for tuberculosis supplemented by the irradiation of the nodes with ultraviolet light or short x-ray exposures and streptomycin. Complete

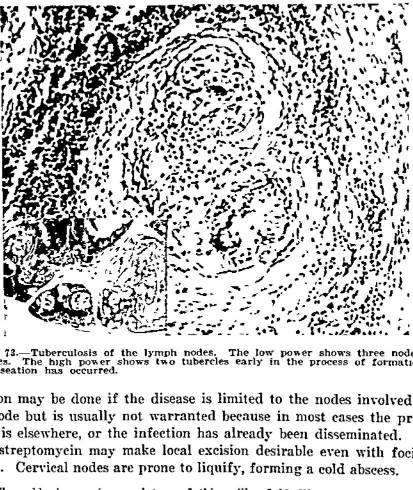

Fig. 73.—Tuberculosis of the lymph nodes. The low power shows three nodes with tubercles. The high power shows two tubercles early in the process of formation, before caseation has occurred.

excision may be done if the disease is limited to the nodes involved or to one node but is usually not warranted because in most cases the primary focus is elsewhere, or the infection has already been disseminated. However, streptomycin may make local excision desirable even with foci elsewhere. Cervical nodes are prone to liquify, forming a cold abscess.

The cold abscess (accumulation of thin milky fluid filled with lymphocytes) is said to contain Much's granules. These are fragments of tubercle bacilli which act as antigens in an unfavorable environment and may actually stimulate local immunity. When injected into sensitized or susceptible animals they may produce the disease. Rollier believes that psoas abscess has a favorable effect on tuberculous spondylitis (Pott's disease). The presence of immune bodies has not been demonstrated definitely in this liquefied material The danger is that of secondary infection, to which it seems to be poorly resistant.

Ordinarily a cold abscess should not be molested. In cases, however, where such an abscess is about to break as a result of pressure necrosis, or where there is secondary infection or *interference with function* (swallowing or breathing, or a rapid increase in size), the fluid may be *aspirated* through healthy tissue. This with streptomycin plus penicillin or sulfonamides, is usually sufficient. Should aspiration fail, and it often does, then incision with curettement of the gland or glands or their excision is indicated. If the primary foci are the tonsils, they should be removed. Small groups of nodes may be excised completely.

Tabes Mesenterica

Tabes mesenterica is tuberculosis of the mesenteric glands and is also usually due to bovine strains. The diagnosis is difficult but is often suspected. Two types of symptoms may occur. Those which arise from intestinal dysfunction (namely nausea, vomiting, flatulence, diarrhea) and those which give rise to pain resembling appendicitis. In both groups there is some fever and malaise. Leucocyte counts are low. These same symptoms are seen in nonspecific mesenteric lymphadenitis (Chapter 20) and diagnosis may be established only after operation and microscopic study of a lymph node.

Treatment.—*The only treatment* is the general care of tuberculosis, including streptomycin, unless there is interference with intestinal function or associated tuberculous peritonitis. Prognosis is good.

Tuberculous Peritonitis

Two clinical and pathological types are seen. (1) In the *ascitic* or *exudative* type, which occurs in young persons, the abdomen fills with clear fluid (ascites) and the intestines are studded with tubercles without demonstrable cause. (2) In the *fibrotic* or *fibrocaseous* (proliferative) type the intestines are matted by adhesions and areas of caseation are found. Sometimes both types are present simultaneously.

Some regard the fibrocaseous type as the late stage of the exudative type.

The portal of entry is said to be in the Fallopian tubes in girls and in the appendix in boys. However, the mesenteric nodes, spleen, and intestines may act as foci. It is perhaps best to regard most cases as hematogenous in origin. Simple exploration and exposure to air sometimes effectuates a cure.

The reason for the beneficial effect of laparotomy in exudative tuberculous peritonitis is not entirely clear. It may be due to the intestinal splinting following laparotomy, to the presence of air (some advocate pneumoperitoneum by air injection as good treatment, just as is done in pneumothorax), or to the reactive hyperemia that is set up, with attraction of phagocytic cells.

In the first type the appendix and/or the tubes may be removed. In the second type this is sometimes necessary, but is apt to be followed by intestinal fistulas.

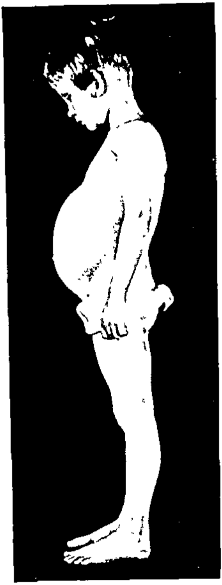

Fig. 74.—Tuberculous peritonitis, with ascites.

Tuberculosis of the Intestines

Tuberculosis of the intestines is also commonly caused by the bovine strain, although the human strain frequently causes a tuberculous enteritis. A chronic type attacks the lymphoid tissue of the ileum (tuberculosis affects lymphoid tissues throughout the body). Due to the fact that tuberculosis spreads along the lymphatics and that in the intestine the lymphatics encircle the bowel, the ulcers that form are known as *girdle ulcers,* in contrast to typhoid ulcers which spread in Peyer's patches with the long axis of the bowel. These contract and produce symptoms of bowel obstruction. Frequently the tuberculous mass is very large and can be felt at the ileocecal valve (where the lymphoid tissue is abundant).

The disease in this region may thus be of three types: (1) Ulceration of the ileum or cecum with or without perforation, (2) hyperplastic ileocecal tuberculosis, or (3) tuberculosis lymphadenitis. All types respond well to streptomycin therapy unless irreversible changes have occurred. The ulcerative type may require surgery to relieve intestinal obstruction due to fibrosis. Here a short-circuiting operation or resection is indicated. Hypertrophic ileocecal tuberculosis requires resection of the terminal ileum, cecum, and ascending colon with ileotransverse colostomy if feasible. If not, a sidetracking operation may be done. Glandular tuberculosis requires surgery to relieve a cold abscess (aspiration) or obstruction due to pressure or adhesions from the nodes. The abdomen is closed without drainage in all types and the general treatment for tuberculosis is instituted. This includes streptomycin and also aureomycin.

Tuberculosis of the Anus and Rectum

Only about 3 per cent of the cases of fistula in ano are said to be due to tuberculosis. The diagnosis is made after examination of excised tissue. This is seen sometimes in infants, where general treatment is all

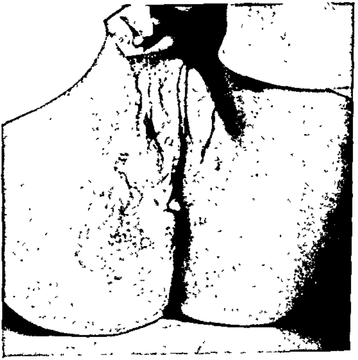

Fig. 75.—Tuberculosis of the perineum. Note the induration and multiple draining sinuses.

that is necessary. In adults, excision of the fistulous tract is required. Rectal tuberculosis is characterized by ulceration which causes pain, tenesmus, and even partial obstruction should a fibrotic structure result. A temporary colostomy may be necessary to divert the fecal current so that

healing may occur. Structures may be dilated or cut on the posterior wall of the rectum. Streptomycin may be used intramuscularly and locally as well. Sometimes resection of the rectum is necessary.

Tuberculosis of the Female Genital Tract

In women the reproductive organs are commonly affected by tuberculosis, although less commonly than the lungs, intestinal tract, and peritoneum. In almost every case of genital tract tuberculosis the Fallopian tubes are involved. The uterine endometrium is often affected—the ovaries in about one-third of the cases. The disease is always secondary although previously it was thought to ascend through the vagina and cervix—organs rarely involved. The primary focus is in the lungs, lymph nodes, or intestines. Tuberculosis peritonitis of the fibrocaseous type is a usual complication in adults. In children the lesions may be superficial and are accompanied by the ascitic or exudative type of tuberculous peritonitis. Such lesions may resolve spontaneously or after celiotomy. The symptoms vary with the type and degree of infection. In children there may be vague pains in the pelvis with indigestion, weight loss, fever, some distention, nausea, and vomiting. Appendicitis, mesenteric lymphadenitis, dermoid or other ovarian cysts, or anomalies may be simulated. In adults the disease resembles chronic pelvic infection produced by gonorrhea. There may be leucorrhea, pelvic pain, menstrual disturbances, sterility, or pelvic masses. Later the bladder and intestines may be involved producing signs of cystitis and intestinal obstruction. In all instances there may be evidence of tuberculosis elsewhere and the general picture of a chronic febrile malady. Since the diagnosis is often difficult, even with diagnostic curettage, exploration is indicated in the early stages. If the disease is not far advanced and is not the fibrocaseous variety, hysterectomy and bilateral salpingo-oophorectomy should be done. In children simple laparotomy may result in resolution. In the late stages surgery is apt to be useless, and it may be followed by multiple fecal fistulae and death. In all cases the general treatment of tuberculosis is indicated, including streptomycin.

Tuberculosis of the Genitourinary Tract

Tuberculosis frequently attacks the kidneys, ureter, bladder, and occasionally the epididymi, seminal vesicles, and testes. The disease is secondary to pulmonary tuberculosis or other foci in most cases. Ten per cent of all patients dying of tuberculosis have kidney involvement. Usually one kidney is involved. This phenomenon is said to be due to differences in resistance in the two organs. The renal cortex or pyramids are first affected; then the kidney pelvis, ureter, and bladder succumb. Almost any type of tuberculous manifestation may be seen—small tubercles throughout the kidney disseminated by the intertubular lymphatics (diffuse type), limitation to the pelvis (pyelitis type or pyonephrosis type), com-

plete destruction of the kidney, occlusion by the ureter with kidney atrophy (autonephrectomy)—or there may be calcification. The bladder is involved early, beginning often about the ureteral orifices.

The symptoms begin with frequency of urination. Later there is urgency, and finally incontinence. The urine is usually bloody which later becomes muddy due to lymphocytes, cellular debris, and bacteria.

The diagnosis is made by x-ray (retrograde pyelogram), the finding of tubercle bacilli in the urine, or the injection of the urine into a guinea pig with positive results. The treatment is general in character, with streptomycin later; nephrectomy may be done if the disease is advanced in one kidney. If the epididymis, seminal vesicles, and testicles are involved, *orchidectomy*, *epididymectomy*, and *seminovesiculectomy* are done.

Pleural Tuberculosis

Pleural tuberculosis is secondary to pulmonary infection in most instances; occasionally it results from tuberculous lymphadenitis of the mediastinal lymph nodes, and rarely it is said to be primary. The incidence of this form of tuberculosis has increased greatly since the employment of artificial pneumothorax. It is probably a complication in a mild or more severe form in 50 to 75 per cent of patients on whom this therapy is employed. Tubercle bacilli gain entrance to the pleural space from tubercles adjacent to the visceral pleura, bronchopleural fistulae, spontaneous rupture of pulmonary lesions (spontaneous pneumothorax), or tuberculous lymph nodes. Two clinical types are seen: pure tuberculosis and tuberculosis with pyogenic infection. The former causes the formation of variable amounts of straw-colored, more or less turbid fluid (pleural effusion); the latter is purulent and may be due to the tubercle bacillus alone (tuberculous empyema) or to an associated pyogenic infection (mixed tuberculous empyema). The diagnosis is established by clinical symptoms and signs, x-ray examination, and thoracentesis. It may be difficult to find the tubercle bacillus in the fluid, in which case guinea pig inoculation should be done. Treatment of the pleural effusion type depends upon its amount and the condition of the underlying lung. If very small in amount with moderate lung collapse and minimal involvement, it should be unmolested. Here it is said to be useful in causing immobilization to some extent of the affected side and it may be well tolerated if streptomycin is used. If more than a very small amount is present repeated aspiration with or without thoracoplasty, depending on pulmonary involvement, is the treatment of choice. Since it is impossible to detect the amount or degree of pulmonary disease without x-ray picture of the lung, this should be done immediately after aspiration of the fluid. Some phthisiologists suggest incomplete aspiration (to prevent adhesions between visceral and parietal pleural) and pneumothorax in lesser degrees of lung involvement. Tuberculous empyema may be treated by aspiration with irrigation using streptomycin or penicillin or both. This form of therapy is not apt to be successful and will fail in the mixed type where

open drainage must be done. If the pleura is not greatly thickened, thoracoplasty will obliterate the pleural space. If the pleura is thick and unyielding, then thoracoplasty with resection of the underlying pleura (visceral and parietal pleural decortication) is done in stages. (See Chapter 19.)

If the lung will not expand sufficiently after decortication to obliterate the cavity even with the aid of thoracoplasty, then the cavity is filled with muscle and skin flaps.

Tuberculous Laryngitis

Tuberculous laryngitis is a complication of pulmonary tuberculosis. It responds well to streptomycin.

Pulmonary Tuberculosis

The diagnosis of pulmonary tuberculosis is made by all factors considered as outlined earlier in the chapter. Recently many x-ray features have been reinterpreted. The childhood type may resemble almost any lesion, and calcification is seen in coccidioidal infections; also in histoplasmosis. Therefore the diagnosis cannot be made by x-ray picture alone.

Surgery is playing an increasingly important role in the treatment of pulmonary tuberculosis. As in all locations of the disease, the general treatment including streptomycin is paramount and all local measures must be looked upon as adjuvants.

All types of surgical treatment are designed to remove the principal focus of the disease (lobectomy or pneumonectomy), to put the part at rest (collapse, compression), or to effect drainage (closed or open). This same philosophy is the guiding principle in the treatment of tuberculosis anywhere. Since securing rest is necessary to the treatment of most surgical cases, it should be considered first. Immobilization and compression of the lung reduces the size of alveoli and bronchi, preventing aeration. Immobility invites chronic passive hyperemia and lymph flow is retarded. This diminishes the absorption of toxins, improving the patient's general resistance. There results also a proliferation of connective tissue which limits and demarcates affected areas often obliterating cavities and pericavity lesions. An exudative process is then converted into one that is proliferative or fibroid. Expectoration is facilitated with the lung at rest and compressed and relaxed, ridding the lung of secretions and accumulated exudates and preventing their reaccumulations.

As in other tissues the disease may be predominantly exudative, caseous, or ulcerative; proliferative, productive, or fibrous. Needless to say, any or all types may be present in the same lung. Healing is accomplished as in other tissues by fibrosis and calcification. Nature in her attempt at spontaneous healing resorts to methods which the surgeon seeks to emulate. In the exudative type with a small fuzzy apical lesion (by x-ray) resolution is common. Here nature may require an effusion to

help her immobilize the tissue and by low fever, malaise, and anorexia she forces the patient to bed. In the caseous varieties more strenuous efforts are required of natural defenses. Patients are sicker, having fever of greater magnitude, night sweats, and loss of weight with prostration. The cavity may be obliterated by immobilization and an attempt at collapse produced by approximation of ribs, elevation of the diaphragm, and pulling over of the mediastinum to the affected side. The fibrous type indicates a good reaction to a disseminated process and will heal if cavitation is not present.

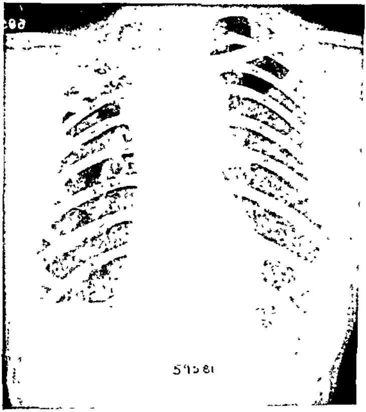

Fig. 76.—Healed tuberculosis of the lungs, adult type. The lesions are calcified.

Types of Surgical Therapy.—Indications for various types of procedures will differ with different clinicians, certainly in minimal and moderately advanced lesions, a sustained period of bed rest should be tried first. This may be supplemented by the use of streptomycin if healing is not prompt. If progress is not satisfactory, *collapse* therapy is indicated. If the lesions are far advanced, *compression* is used so that cavities may be obliterated. Collapse therapy is usually accomplished by *intrapleural artificial pneumothorax.*

Intrapleural Pneumothorax.—This is the most widely used form of treatment and is started by some phthisiologists after a trial of bed rest for thirty to sixty days. The cushion of air places the lung at rest and permits it to relax. However, it is usually started after bed rest for

four to six months and where hemoptysis is a prominent symptom and where the lesion is predominantly unilateral. It may be necessary to refill the pleural cavity with air for many years and it is always necessary to continue bed rest after pneumothorax has resulted in negative sputum. If adhesions exist between the visceral and parietal pleura, collapse may not be complete but should be tried. If results are not satisfactory these adhesions may be divided by intrapleural pneumolysis either as a closed operation (thoracoscope) or through an open thoracotomy (when adhesions are broad). Such adhesions are demonstrated by x-ray and fluoroscopic examination after pneumothorax and obviously pneumothorax must be continued after their division or the lung will become adherent to the chest wall again. Cavities may collapse whether adhesions are present or not. If they do not, other measures are used such as intrapleural pneumolysis, transpleural aspiration (Monaldi), external drainage (cavernostomy), or thoracoplasty (see cavitation). Partial pneumothorax may be used on both sides if vital capacity permits. Since tuberculous tissue collapses more readily than the normal, pneumothorax is said to be selective. It must be continued for two years or more to obtain the best results. Contraindications to its use are extensive bilateral involvement, asthma, advanced emphysema, and serious coexisting disease. Complications of the procedure are "pleural shock" (which is probably due to the administration of air, or traumatizing the lung) air embolism, serous effusion, tearing of adhesions, rupture of a superficial cavity, hemorrhagic effusion, secondary infection with empyema, tuberculous empyema, pleuropulmonary fistula, and tension pneumothorax as a result of tearing the lung.

Pneumothorax should be induced every two to three days at first; then as the air is less readily absorbed every week or two. With the needle in the seventh interspace the water manometer will fluctuate between −7 and −12. This shows a "free" rather than adherent pleural space. About 300 c.c. of air are given at the first sitting. This should reduce the manometer readings. With the aid of the fluoroscope and manometer, air is injected at intervals until complete collapse is obtained and the manometer shows little fluctuation, −1 to −3.

Extrapleural Pneumothorax.—This procedure has been used in cases of bilateral, apical disease of the lungs with cavities and also in patients who have dense adhesions between the visceral and parietal pleurae. The operation is not mutilating, can be done in one stage, and is a reversible procedure. *Technique*: Usually the fourth rib is resected after the periosteum is incised and then a cleavage plane is established between the parietal pleura and the endothoracic fascia. The lung is freed from the thoracic wall extrapleurally down to the sixth or seventh rib posteriorly, anteriorly to the fourth rib, and medially as far as the mediastinum. The space is filled with sterile saline solution and the incision is closed. Subsequently this space is filled with air in sufficient amounts to maintain a collapse.

Pneumoperitoneum.—Pneumoperitoneum is a procedure sometimes used in bilateral pulmonary tuberculosis, especially if basal. Air is injected under the diaphragm on both sides. It is used above or in conjunction with other forms of collapse therapy.

Intrapleural Pneumolysis.—Sometimes adhesions prevent collapse. These may be divided by the "closed" method with the aid of a thoracoscope (Jacobaeus, Coryllos) or the "open" method by incising the pleura and dividing the adhesions under direct vision after doubly ligating them. The dangers of the closed method are injury to the lung with resulting tension pneumothorax or bronchopleural fistula (therefore, adhesions are divided close to the chest wall), effusion and empyema, hemorrhage from lung tissue or directly from the great vessels, and injury to the pericardium. The open method is safer and permits ligation or cauterization of all vessels so that broad bands may be severed.

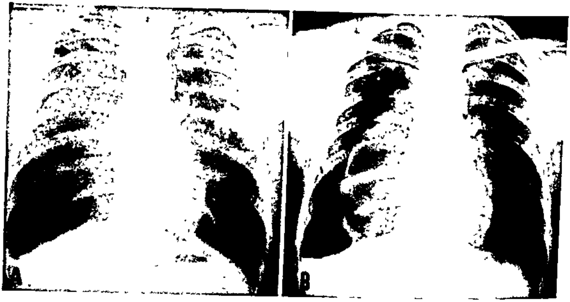

Fig. 77.—Cavitary tuberculosis treated by open pneumolysis (pneumonolysis); and pneumothorax. Patient, F. P. F., was a man aged 45 years. Cavitary tuberculosis of the right apex was present. The sputum was positive.

A. X-ray picture, arrow points to the cavity in the right apex and a dense adhesion between the visceral and parietal pleura Artificial pneumothorax was started, but this could not be effective because of the dense adhesions.

B. X-ray picture showing the effect of pneumolysis and artificial pneumothorax. There is good collapse four months after the operation. Sputum which was positive before surgery is negative now and was for fifteen consecutive daily sputum analyses. The operation was done under local anesthesia in the midaxillary line in the third interspace. Ribs were spread apart and the adhesions were divided and tied so that there would be no bleeding. By the open method it is possible to divide broader bands than it is by the closed method which may be done through the use of the thoracoscope. (Case referred by Dr. Russell Henry.)

Interruption of Phrenic Nerve.—This procedure produces a paralysis of the diaphragm, making it entirely passive. Usually it rises to a degree depending on intrathoracic pressure as influenced by adhesions or effusions and intra-abdominal pressure. Sometimes there is paradoxical movement (see chapter on empyema). It is said to reduce the volumetric capacity of the chest from one-sixth (400 c.c.) to one-third (800 c.c.) (Hegner).

The nerve may be crushed (phrenic emphraxis), cut (phrenic neurectomy), or avulsed (phrenic exeresis). Crushing the nerve produces a paralysis of the diaphragm for about six months. Accessory phrenics are occasionally encountered. They must also be crushed. Phrenic division produces a permanent paralysis. In avulsion the accessory nerve is usually removed with the main branch. Although usually a simple procedure, many complications may occur unless care is exercised. Hemorrhage, air embolism if one of the large veins or arteries are injured, tearing of the thoracic duct, and injury to other nerves (recurrent laryngeal, vagus, cervical plexus) in avulsion have been reported. If the nerve is avulsed, mediastinal hemorrhage or injury to the pericardium or lung may occur. Because of its dangers, phrenic avulsion is to be condemned and is no longer employed by most surgeons.

The indications vary with different observers. Some believe the procedure to be useless or to be actually contraindicated because the upper part of the lung may actually have to work more to compensate for the relative inactivity of the lower lobes. Others prefer it to pneumothorax. In general it may be looked upon as an adjunct to pneumothorax or thoracoplasty, particularly in lesions in the lower chest. However, the operation does stop the pumping action of the diaphragm and gives rest to the lung and it also decreases the size of the lung and allows it to relax, thereby facilitating healing.

Thoracoplasty.—Compression of the lung is best secured by the subperiosteal resection of ribs over the affected side. Should symptoms persist after pneumothorax and phrenicotomy, thoracoplasty may be used. Usually fever, cough, hemoptysis, and positive sputum result from persistence of a cavity. However, chronic fibrotic lesions without cavities or severe hemorrhage with cavities that do not readily collapse may not respond to pneumothorax and may require thoracoplasty. Fluoroscopic examination after the introduction of 200 to 300 c.c. of air will reveal the stability of the mediastinum (see Chapter 19). If fixed, mediastinal flutter will not occur after thoracic compression operation. However, a pneumatic jacket is put on to prevent parodoxical respiration.

Thoracoplasty has other indications than those mentioned; namely, chronic empyemas, tuberculous or pyogenic. It should not be used if there are recent lesions in the other lung or elsewhere in the body or in the presence of severe asthma, emphysema, or associated debilitating disease (diabetes, nephritis, heart disease). The operation is serious, requiring careful preparation of the patient. It should be done in stages. Often resection of the upper three ribs is sufficient. Usually three or more stages are required, two to three weeks apart, depending on the patient's reaction to the procedures. In this way the upper ten ribs may be removed. The first stage usually is the most difficult, for here the first, second, and usually the third ribs are removed. The third rib is removed first and then the superior ribs in sequence, leaving the first rib for attack after ample space has been secured by the removal of the lower ribs. The

Fig. 78.—Phrenic crush. *Basal tuberculosis* of the left lower lobe, treated by *phrenic crush* The patient, J. R., a woman 42 years old, had tuberculosis of the left base and a persistently positive sputum. Pneumothorax was unsuccessful in arresting the progress of the disease. The patient also had a tuberculous laryngitis. This was an ideal case to be treated by immobilization of the diaphragm. Accordingly, a phrenic crush was done. The diaphragm in its paralyzed condition rose to a high level, immobilizing lower lobe. This procedure was repeated on several occasions. The patient has remained well. The sputum has been negative.

The operation is done under local anesthesia through a small transverse incision above the clavicle and lateral to the lateral border of the sternocleidomastoid muscle The operation of phrenic crush is to be employed when the diaphragm is immobilized for short periods only. This, as the name implies, consists of crushing the nerve with a hemostat. Phrenicotomy is a division of the phrenic nerve and is to be used where a more permanent paralysis is desired. If regeneration is not to take place, a small piece of the phrenic nerve should be excised. This is known as phrenicectomy. The old operation of phrenico-exeresis is no longer employed because of its dangers and also because it is unnecessary.

A. November, 1945. Cavitary tuberculosis of left base. *B*. February, 1946. Diaphragm in paralyzed position. Cavities not discernible. *C*. January, 1948. Cavities open again Diaphragm in normal position. *D*. February, 1948. Phrenic crush—diaphragm high and immobile. *E*. July, 1949. Lung healed. Diaphragm resumes its normal function. (Referred by Dr. David Stone.)

transverse processes of the vertebrae are usually removed in order to prevent the collapsed lung and its cavity from falling into the paravertebral gutter, thereby escaping compression. Some surgeons remove the posterior portion of the ribs through small posterior incisions and the sternal portions through anterior incisions. Usually an adequate posterior incision with careful hemostasis permits a complete removal of the ribs. Local anesthesia, supplemented with intravenous Pentothal Sodium, may be used. Our preference is ether by endotracheal tube.

Thoracoplasty produces a collapse of the cavernous lung and results in an arrest of the disease in over 90 per cent of the patients. The mortality varies between 5 and 10 per cent, depending upon the type of risk which is selected. The procedure is, of course, irreversible and does produce some deformity. It is not useful in bilateral tuberculosis.

Fig. 79.—Thoracoplasty in the treatment of cavitary tuberculosis. A. K., a woman 38 years of age, with cavitary tuberculosis of the right upper lobe. Widespread adhesions between the visceral and parietal pleura made it impossible to use artifical pneumothorax. Conservative treatment was ineffective.

A. X-ray photograph showing cavity in right upper lobe. *B*. X-ray photograph showing the effect of a two-stage thoracoplasty in which the upper three ribs and transverse processes were removed in the first stage, and then two weeks later the fourth and fifth ribs were removed together with the transverse processes This is selective collapse and, in addition, it does not compress the hilus, thereby reducing vital capacity. Sputum analysis done recently is negative (Caso referred by Dr. Russell Henry.)

Chronic Cavities.—Chronic cavities which do not respond to the foregoing procedures may be obliterated by other methods. Sembs' *apicolysis* detaches the apex of the lung from its attachments, permitting the apex of the lung to collapse downward. This is done is addition to resection of the first three ribs. *Oleothorax* is the injection of oil instead of air to collapse a cavity. The oils employed are Gomenol, Iodipin, paraffin oil, and olive oil. Since oil is more slowly absorbed than air, its sustained effect is said to be of more value than pneumothorax. It is not widely used in this country. Like oils injected elsewhere (bronchi, spinal canal), it may be very irritating. It should be aspirated after this treatment is aban-

doned. Plombage or the injection of paraffin plombes into the pleural cavity belongs in this group.

Scaleniotomy or cutting of the scalene muscles is used in combination *with other operations such as phrenectomy. As has been pointed out,* the latter immobilizes the base of the lung, but throws more work on the apex. With excision or division of the scalene muscles which are accessory muscles of respiration, the apex, too, is immobilized.

Tension cavities, *in which air may enter but due to a valvular mechanism* from a kinked bronchus or mucosal flap it cannot leave, are benefited by aspiration and suction as in closed drainage of the pleura. Monaldi, Vineberg, and others introduce a needle and then a small tube through the intercostal space. *The pleural surfaces must be adherent. Gentle suction* is then applied.

Fig. 80.—Thoracoplasty. Seven-rib thoracoplasty in the treatment of left upper lobe cavitary tuberculosis. The patient, S. M., was a woman 32 years of age who had three cavities in the left upper lobe, the largest measuring approximately 3 cm. in diameter. The lowermost cavity was in the lower portion of the upper lobe close to the lingula. A two-stage thoracoplasty was done. The first three ribs, together with the transverse processes, were removed at the first stage, and the second stage included the fourth, fifth, sixth, and seventh ribs together with the transverse processes. A five-rib or a seven-rib thoracoplasty must be done so that the scapula will not ride inside and outside of the sixth rib when this is left in place

The effects of seven-rib thoracoplasty are demonstrated in the x-ray photograph. Note the *collapse not only of the left upper lobe, but also a compression of the left lower lobe* which has occurred due to the scoliosis, with the convexity toward the operated side together with a narrowing of the lower ribs. This is not as selective as is to be desired because the function of the entire lung has been practically eliminated. This patient was last seen in June, 1949. The sputum did not contain any tubercle bacilli at that time.

Open incision (*cavernostomy*) *and drainage as for a lung abscess* is used in cases where other methods fail to collapse the cavity. The procedure was formerly employed and then abandoned because of a persistent tuberculous bronchopleural fistula. The use of streptomycin and penicillin help prevent this. Its use is limited to the peripheral *cavity in which* lobectomy is contraindicated and may be looked upon as a supplementary procedure to thoracoplasty.

Fig 81.—Lobectomy in tuberculosis. Lung resection in tuberculosis is indicated in the following conditions: (1) uncollapsed cavities following thoracoplasty, (2) tension cavities which failed to close under pneumothorax treatment as a result of bronchial disease; (3) cavities situated in the lower lobes which do not close under pneumothorax or with the aid of phrenic interruption or pneumoperitoneum; (4) bronchial stricture or bronchostenosis causing a shrinkage and bronchiectasis of the lobe; (5) tuberculoma; (6) disease which is stationary but which does not improve under conservative methods or less radical surgical methods. In other words, "a good chronic." By that term is meant a patient whose resistance to tuberculosis is high enough to prevent spread and yet not high enough to arrest the disease completely.

The dangers of lung resection in tuberculosis are many. There is usually a higher mortality, tuberculous empyema is a possible sequel, bronchopleural fistula is another, and spread to adjacent lobes or to other side is still another hazard. Streptomycin has lessened the latter considerably and is used routinely in the preoperative preparation of patients. The eradication of tuberculosis by resection is not to be considered as curative. It is a help in the arrestment of the disease but does not supplant medical management. These patients are all cared for over sufficiently long period of time to ensure a lack of spread. *C.* Photograph of the left lower lobe which possessed three of the indications listed: (1) There is a bronchostenosis, (2) there is a bronchiectasis, and (3) the disease is limited to the left lower lobe. Some tissue has been removed for biopsy. *A.* Bronchogram showing bronchiectasis of left lower lobe with narrowing of left lower lobe bronchus. *B.* Postoperative film taken five days after surgery. The patient, L. B., was a woman 30 years of age who had served with the Armed Forces in the Pacific theater. During this time she developed a cough which was persistent. On several occasions she had hemoptysis and lost weight. The sputum was positive and the x-ray examination demarcated the site of the disease as the left lower lobe. Bronchoscopic examination showed a bronchostenosis of the left lower lobe bronchus. Biopsy from some of the granulation tissue showed tuberculosis. Lipiodol was injected and bronchiectasis was present throughout the left lower lobe. The patient has had no further symptoms since surgery.

The indications for pneumonectomy in tuberculosis are more or less the same as those enumerated above. However, in general, when the disease has spread to a degree which involves the entire lung, the probabilities of arrestment are less than they would be if only one lobe were involved. Consequently, pneumonectomy, while offering much hope at first, has now not been practiced so generally. The entire question concerning extirpative procedures in the treatment of pulmonary tuberculosis rests upon the theory that the treatment is necessarily one of complete rest to the part involved as well as to the individual as a whole. In doing a lobectomy it is easily understood that the remaining lobes will undergo at least a compensatory emphysema to fill the space occupied by the removed lobe. Furthermore, it is conceivable that that remaining lobe would have to carry on a greater amount of work since per unit of space the number of alveoli have been decreased. The same holds true for pneumonectomy. The question naturally arises as to whether or not the added work induced by the removal of one lung or a part of a lung to the remaining lung tissue will act in an adverse manner so as to propagate the disease or invite a spread. To curtail the latter objection perhaps the use of thoracoplasty on the operated side, either selective in lobectomy or total in the case of pneumonectomy, may be helpful. Curtailment of expansion of remaining lung tissue would, of course, reduce vital capacity. There, again, the question arises as to how much crippling will be induced by extirpative surgery in addition to collapse therapy. (Referred by Dr. R. M. Vandivier.)

Lastly, in those cases of persistent cavitation, hemorrhage, or tuberculous tracheobronchitis which do not respond to streptomycin, pneumothorax, or phrenectomy, *lobectomy* or *pneumonectomy* may be indicated. (See Chapter 19.) These procedures carry a higher primary mortality in tuberculosis than the other operations which have been described and may be followed by serious sequelae such as spread to other lobes or the other lung, tuberculous empyema, or tuberculous bronchopleural fistula, or both. The use of streptomycin has reduced their incidence, making lobectomy relatively safe. Pneumonectomy is far more serious not only because it is a more extensive operation but what is more important, it indicates a more widespread dissemination of the disease. *In general extirpative operations are indicated in "good chronics"—patients who have lived with the disease for years without being cured in spite of various types of treatment and yet the disease has not spread to any great degree.* Indications are not clearly defined for lobectomy and pneumonectomy but at present we have employed them in (1) persistent tension (check valve) cavities with surrounding fibrosis; (2) tuberculoma; (3) tuberculous cavitation with bronchiectasis; (4) persistent unilateral or lobar tuberculosis of one side which has not spread to the opposite lung but which has not responded to less formidable procedures (permanent collapse procedures); (5) severe bronchial stenosis; (6) very large cavity; (7) hilar cavity; (8) lower lobe cavity; (9) progressive cavitary disease; (10) bilateral localized disease; (11) bronchopleural fistula.

Bone Tuberculosis

Bone tuberculosis is probably never primary. The original focus is in the lungs, lymph nodes, or gastrointestinal tract. The bones and joints are secondarily involved through the blood stream by involving capillaries already diseased by the tuberculous toxemia. Clumps of bacteria produce infarcts with tubercles as in other tissues. These are seen first in the metaphysis with subsequent involvement of the epiphysis and neighboring joints. Destruction of bone and joint results with deformity and cold abscess formation (see Chapter 21). Symptoms include swelling, muscle spasm which may be easily detected since the disease is usually monarticular, atrophy of surrounding soft tissue, usually out of all proportion to the disease of the part, pain, and deformity due to voluntary position, muscle spasm, or contracture. The diagnosis is made by a careful history, the general symptoms and signs of the disease with or without the discovery of the primary focus, x-ray examination, skin tests, and biopsy.

Tuberculous spondylitis (Pott's disease) causes a destruction of the vertebrae with subsequent collapse of the vertebral body and a resultant kyphosis. Frequently a cold abscess forms and follows the psoas muscle down to the femoral region (iliopsoas abscess) beneath the inguinal ligament. In the cervical region the abscess extends anteriorly and may burrow into the thorax. The treatment includes bed rest, with *immobiliza-*

tion by a frame or plaster cast, and the use of streptomycin. Spinal fusion *may be necessary*. In children, bed rest and sunshine may produce a cure.

Rollier of Leysen, Switzerland, believes that prolonged immobilization produces muscle and bone atrophy, thus decreasing local immunity. He prefers some motion, with rest in the sunshine on millet seed bags.

Fig. 82.—Advanced tuberculosis of the spine (Pott's disease), with kyphosis.

The hip, knee, ankle, shoulder, elbow, or wrist may be involved. Usually only one joint is affected. The part is immobilized to produce ankylosis in the most favorable position. (In children if treated early and persistently some degree of motion may be saved. Conservative measures are the rule with the aid of braces and casts. In adults operations are used to produce a bony ankylosis, arthrodesis.)

Lastly, in those cases of persistent cavitation, hemorrhage, or tuberculous tracheobronchitis which do not respond to *streptomycin, pneumothorax,* or phrenectomy, *lobectomy* or *pneumonectomy* may be indicated. (See Chapter 19.) *These procedures carry a higher primary mortality in tuberculosis than the other* operations which have been described and may be followed by serious sequelae such as spread to other lobes or the other lung, tuberculous empyema, or tuberculous bronchopleural fistula, or both. The use of streptomycin has reduced their incidence, making lobectomy relatively safe. Pneumonectomy is far more serious not only because it is a more extensive operation but what is more important, it indicates a more widespread *dissemination of the disease. In general extirpative operations are indicated in "good chronics"—patients who have lived with the disease for years without being cured in spite of various types of* treatment and yet the disease has not spread to any great degree. Indications are not clearly defined for lobectomy and pneumonectomy but at present we have employed them in (1) persistent tension (check valve) cavities with surrounding fibrosis; (2) tuberculoma; (3) tuberculous cavitation with bronchiectasis; (4) persistent unilateral or lobar tuberculosis of one side which has not spread to the opposite lung but which has not responded to less formidable procedures (permanent collapse procedures); (5) severe bronchial stenosis; (6) very large cavity; (7) hilar cavity; (8) lower lobe cavity; (9) progressive cavitary disease; (10) bilateral localized disease; (11) bronchopleural fistula.

Tuberculosis of Other Tissues

Tendon sheaths, the skin, and many other organs of the body are frequently involved. As was previously stated, no organ or tissue is immune.

SUMMARY

The diagnosis of tuberculosis is relatively easy. The treatment may be summarized as: first, the general treatment of tuberculosis; secondly, local eradication, or arrest, by measures designed to localize the infection. It is readily seen that since there is no specific treatment of the disease, its successful management depends upon the care, rather than the cure, that the physician offers. Although streptomycin approaches a specific therapeutic agent in some types of the disease, it is the patient's resistance that produces a cure. The care of the tuberculous patient is based upon the theory that the disease will cure itself if the patient's general state of health is improved and the involved area is put at rest. Rest, then, to the body as a whole and to the affected part, and good food, fresh air, and sunshine, together with encouragement, constitute the chief methods of treatment. Streptomycin, para-aminosalicylic acid, and other antibiotics and chemotherapeutic agents constitute a formidable attack on the favorableness of the environment for bacterial growth and on bacterial proliferation. Many of the newer agents are still in the experimental stage. More will be forthcoming. The surgeon aids in securing arrest (1) by excising diseased tissue (lymph nodes, kidney (Fallopian tubes, lobes of lung, etc.); (2) by immobilizing bony parts through destruction or fixation of opposing surfaces (arthrodesis) or implantation of bone (Hibbs' or Albee's method

in two or three weeks. This constitutes the primary state of the disease and lasts until secondary symptoms appear six to twelve weeks later.

Secondary Stage.—The next stage may be looked upon as the dissemination of the germ and its toxins through the blood stream to all parts of the body. There is a syphilitic septicemia. Consequently, there are general symptoms and signs, such as fever, malaise, anemia, and

Fig. 84.—Chancre of the lip.

Fig. 85.—Chancre. Note the perilymphatic and perivascular round-cell infiltration.

general aching sensations. In addition, there are local manifestations. The first to appear is a *cutaneous rash* over the entire body. It may be macular, papular, pustular, or vesicular in type and involves even the palms and soles.

Mononuclear cells play the greatest part in secondary syphilis. If pustules form there may be many polymorphonuclears. Giant cells and fibroblasts are also seen.

Chapter 9
SYPHILIS

Syphilis is a contagious disease caused by the *Treponema pallidum (Spirochaeta pallida)* and transmitted by contact, usually venereal (acquired syphilis) or by inheritance from the mother (congenital syphilis).

The father infects the mother and she transmits the disease to the fetus. Some claim that the sperm may carry the treponema. However, the mother always has at least a latent syphilis and therefore the mother of a syphilitic infant shows an "immunity." The more recent the disease in the parent, the greater the chance for congenital syphilis in the offspring. The father with late tertiary syphilis, is not apt to infect mother or child.

The name *lues* means "plague" and is used often among physicians to conceal the identity of the disease in talking before patients. In Chapter 1 we learned that in 1530 Fracastorius wrote a poem about a shepherd, "Syphilis," who was afflicted with the "big pox" because he had blasphemed the Lord. Although the disease had been well known before and had been called the "big pox" to distinguish it from "small pox," the name of the fictitious, sacrilegious shepherd has clung to this affliction. It was not until 1905 when Schaudinn and Hoffman identified the small spiral, motile *Treponema pallidum* that the true cause of the disease was known. Then, in 1910, came the "curative" remedy of Ehrlich which we now know is only partially curative: salvarsan (arsphenamine and neoarsphenamine).

THE THREE STAGES OF ACQUIRED SYPHILIS

Primary Stage.—The acquired disease first manifests itself by an initial lesion known as the primary lesion, primary sore, or *chancre.* Usually this is seen on the genitals (glans penis prepuce, labia, vaginal wall, or, rarely, the cervix) about two weeks after exposure, but in some cases it occurs on the lips, and in accidental infection it may be seen on the hand or arm (the latter is seen occasionally in physicians and nurses). This is a painless ulcer which early involves the lymphatics, giving rise to enlarged, hard, painless, discrete inguinal nodes. In animals the organisms reach the regional lymph nodes within five minutes after entrance through the point of origin (Karsner). Since removal of the chancre does not necessarily stop the dissemination of the organism, some observers believe the primary lesion to be a lymphangitis with a local ulcer rather than an ulcer with a lymphangitis and lymphadenitis. The chancre is made up of small lymphocytes, fibroblasts, epithelioid cells, and giant cells (Langhans' type). The small arteries and veins show a thickened intima. This sore causes very little discomfort and disappears with-

Frequently the hair falls out (alopecia) and sometimes the nails are lost (onychia). A second and no less constant symptom is a sore throat. Small grayish *mucous patches* are seen not only in the throat but on the tongue and buccal mucous membrane as well. Condylomata lata occur on the cervix uteri. In addition, there are other lesions such as arthritis, retinitis, and even hepatitis. Frequently there is generalized, painless lymphadenopathy. The moist papules, open skin lesions, and mucous patches are loaded with spirochetes and therefore such patients must be in strict quarantine. Direct or indirect contact will spread the disease. The secondary stage may disappear within three or four weeks, or it may persist through relapse for a longer period. It is sometimes difficult to state when the secondary stage ends and the tertiary begins.

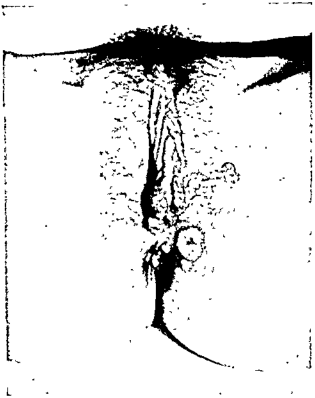

Fig. 87.—Syphilitic condylomata lata.

Tertiary Stage.—The third stage usually appears months or years after the initial lesion but may occur earlier. The lesions of this stage are the gumma (rare), diffuse fibrosis, and vascular changes. There may be tertiary lesions of the skin, mucous membranes, and cervix uteri which ulcerate and contain spirochetes. Gummas may occur in the skin, subcutaneous tissue, bones, muscles, liver, brain, lungs, kidneys, heart, and other organs. They are ulcerative lesions with overhanging edges and necrotic, caseous centers. The diffuse fibrosis or "hardening" which may

A. B.

Fig. 86.—Secondary syphilis. A. Macular skin lesions. B. Mucous patches on the tongue.

There is parenchymal atrophy. Such changes occur slowly over a period of years and imply the presence of the organisms for a long time. Calcification rarely occurs. The older the infection, the less contagious it becomes.

DIAGNOSIS

A history of exposure may or may not be obtained. However, the diagnosis is made by careful physical examination, by laboratory tests, and, if necessary, by therapeutic tests as well. Such routine examinations as eye tests (Argyll-Robertson pupil, inequality of pupils, muscle imbalance), knee jerks (absent in tabes dorsalis), and scars from previous lesions give an adequate lead to the diagnosis. If the patient is seen in the primary stage, a dark-field examination of the exudate from the sore will usually reveal the organism. The same is true of open secondary lesions, especially mucous patches in the mouth or around the genitals. Precipitation tests (such as the Mazzini, Kline, and Kahn tests) and the Wassermann complement fixation reaction aid greatly in the diagnosis. It should be remembered, however, that when negative they do not always rule out the disease and when positive they do not always attest to its activity. In addition to carrying out blood serological tests, the spinal fluid also should be examined for serological tests; the spinal fluid also should be examined for cells, globulin, colloidal gold curve, and Wassermann reaction. Last, if an internal lesion defies exact diagnosis, the therapeutic test is available: antisyphilitic treatment may be instituted and the suspicious lesions may disappear.

PROGNOSIS

The disease is a specific one with specific remedies. If the remedies are early and persistently applied, complete cure should be obtained.

IMMUNITY

There is perhaps some natural immunity to the disease. No doubt many who are exposed do not contract it. Also the disease is self-limited in a few. This is surmised by the occasional patient who has had the disease but who has had treatment. Yet after several years there is no clinical or serological evidence of it. Perhaps it still must be classed as latent. The disease itself may confer an immunity but for how long is unknown. If the disease is cured, then reinfection should be possible. Very few cases of this sort have been reported. Even though there is no clinical evidence of the disease the spirochetes may still be present.

The treatment begins with prevention. The press, governmental agencies, and an enlightened public have at last deemed it advisable to disseminate information concerning this scourge. If it is true that about 3½ per cent of the adult population has or has had the disease, it is well that this campaign is under way

occur in tertiary syphilis is the probable cause of syphilitic cirrhosis of the liver and paresis (hardening of the brain). These lesions, in turn, may be partially, if not altogether, due to the vascular changes that occur. The intima is thickened and forced inward by subendothelial swelling due to small mononuclear endarteritis, which interferes with the blood supply and results in a necrosis of tissue, or, if the process is extremely slow, in a fibrosis. Small round cells also extend widely around the vessels (perivascular round-cell infiltration). This stage may last throughout the entire life of the patient, which is usually shortened because of the disease.

Gummatous lesions may resemble tuberculosis, and as was pointed out in Chapter 8, the coagulation necrosis resembles infarction. The central portion of a gumma is firm, elastic, opaque, and yellowish-white. This is the necrotic, caseous part which does not tend to liquefy. The capsule is made up of dense tissue rich in epithelioid cells and mononuclear wandering cells. Giant cells are also seen. The whole arrangement is indefinite and irregular. This and the characteristic changes in the vessels help to distinguish the lesions. In the aorta, gummatous or diffuse syphilitic infiltration affects the adventitia and media, obliterates and destroys the vasa vasorum, and brings about hyperplastic changes in the intima. Perhaps in syphilis as in other infections, the type of lesion depends on the rapidity of its development since it is essentially vascular. A sudden occlusion might cause necrosis and sloughing, the more gradual may give rise to gumma, and the extremely slow may engender a diffuse fibrosis.

Although the pathological course of syphilis is subdivided as indicated, the biological course is divided into *acute* (first two years) *early latent* (third and fourth years), and the *late latent* (which may last the rest of the patient's life).

The reactions of tissues to syphilitic lesions follow a different course from that seen in nonspecific infections or in tuberculosis.

1. *Resolution* occurs frequently as in the chancre and secondary lesions.

2. *Necrosis and absorption* occur commonly because of a decreased blood supply and an improvement under treatment. The gumma is an example.

3. *Necrosis and sloughing* are seen in untreated cases, especially in bone and cartilage, but also in the skin and elsewhere; for example, saddle nose, sloughing of hard palate, sloughing of large areas of skin, etc.

4. *Suppuration* does not occur, nor does liquefaction take place as in tuberculosis. Occasionally a syphilitic lesion is secondarily infected, with resultant pus formation.

Healing occurs by cicatrization such as follows the destruction of tissue from any cause. There is, however, a "master process" which is frequently an end result regardless of the extent of tissue destruction. This at times is all that may be seen in an organ except for the infiltration of lymphocytes and plasma cells near the blood vessels and lymphatics.

lesion may occur as it does in other organs. Usually, however, the cause of such a process is diffuse scirrhous carcinoma. Other lesions resembling syphilis in the stomach are carcinoma, sarcoma (reticulum-cell and lymphosarcoma), Hodgkin's disease, fungus infections (actinomycosis, blastomycosis), tuberculosis, and anthrax. The diagnosis is suspected because a lesion of this size could be caused by only one other disease, malignant

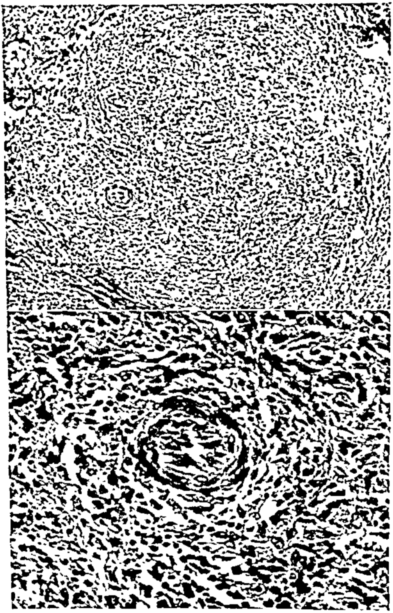

Fig. 88.—Photomicrographs of syphilis in the skin. *A.* (Low power.) Perivascular infiltration. *Note the nodular appearance of the lesion*; also the extent of the perivascular response which is not limited to the immediate circumference of the vessel but extends over a wide area This is important in the concept of this disease (as well as of others). The endothelium is first involved, then its surrounding tissue. *B.* (High power.) Thickened vessel Many lymphocytes, epithelioid, and mononuclear wandering cells are seen. The intima is thickened, as is also the adventitia. The media is partially destroyed.

In the past there were three types of treatment: the arsenicals (neoarsphenamine), the heavy metals (bismuth and mercury), and the iodides. These were employed usually in the order mentioned and were repeated until a cure was permanent. This required two, or even three, years of continued treatment but in most cases resulted in a cure or at least an arrest of the disease. Since the advent of antibiotics, such as penicillin, new strides have been made in the treatment of the disease. It may completely revolutionize the treatment of syphilis. Bacitracin may also help in the treatment.

SYPHILITIC LESIONS IN DIFFERENT TISSUES

Skin Syphilis.—In the primary stage the characteristic lesion is the chancre. In the secondary stage the disease manifests itself by the skin rash, mucous patches, and condylomas (soft warts about the genitals). In the tertiary stage large serpiginous ulcers may develop on the scalp, the chin, and the upper outer side of the leg. Any chronic ulcer of the skin should be studied for this possibility.

Syphilis of the Mouth, Nose, and Throat.—Syphilis of the mouth, nose, and throat is highly contagious. It is characterized in the secondary stage by mucous patches, on the tongue and buccal mucous membrane, and in the tertiary stage by gummatous ulcers of the tongue and floor of the mouth. The tongue ulcers are very often associated with carcinoma. Ulcers on the roof of the mouth (hard palate) frequently penetrate through into the nose, forming a dirty, secondarily infected opening, which permits regurgitation of fluids into the nose. The typical "saddle" nose may be a part of this same process or the result of a necrosis of the septum alone. Congenital syphilis may give rise to a chronic atrophic rhinitis. The discharge is foul—syphilitic ozena. *Diagnosis* is made by serological tests and, more important, repeated biopsies, then the therapeutic test. If healing is not progressing satisfactorily in two to three weeks, excision of the ulcer, especially of the tongue, is indicated for further study.

Syphilis of the Esophagus, Stomach, Intestines and Rectum.—If a patient has stomach or intestinal symptoms and a 4 plus Wassermann, this does not necessarily mean that the symptoms are due to syphilis. However, gastrointestinal lesions do occur in syphilis and may be revealed by gastrointestinal x-ray after barium meal. Syphilitic gummas of the esophagus usually resemble carcinoma. Biopsy should be done. The ulcers heal, leaving a stenosis. This is treated by careful dilation bougies. In the stomach there may be a large, deforming lesion of the fundus or pyloric antrum. Gummas may be single or multiple and are usually found in the submucosa. Gummas may ulcerate and then heal with scars which deform the stomach (hourglass contracture, plyoric stenosis). Formerly a diffuse fibrosis resembling linitis plastica was ascribed to the action of the *Treponema pallidum*. Undoubtedly such a

neoplasia (carcinoma or lymphosarcoma). If it were due to the latter, operation would be useless; therefore, a therapeutic test is tried and its effects observed by frequent x-ray examinations. If no improvement results, surgery is indicated. This may be necessary to relieve obstructions resulting from scar formation. Here gastroenterostomy, gastrogastrostomy, or pyloroplasty may be done. In large ulcerating lesions subtotal gastric resection is done. Rarely total gastrectomy may be necessary to excise all of the diseased tissue. In such instances, the surgeon usually feels warranted in doing the operation because (a) there is no healthy stomach suitable for anastomosis or (b) the possibility of carcinoma has not been completely ruled out.

Syphilis attacks the intestines in the congenital and acquired forms. The *small intestine* may be ulcerated especially in the ileum in the former but rarely in the latter form. Acquired syphilis may affect the colon, especially the sigmoid, the rectum, and the anus. As elsewhere, gummas may form with resulting fibrosis and stricture. In the small intestine or colon the constricted area may produce an obstruction requiring a short-circuiting operation or resection. In the rectum or anus such areas may require excision, but often simply dilatation with antibiotic treatment is sufficient.

Syphilis of the Liver, Spleen, and Kidney.—In the "parenchymatous" organs a diffuse fibrosis is often observed. Acute hepatitis, splenitis, and nephritis are seen in secondary syphilis and fibrosis in tertiary syphilis. The lesions produced are cirrhosis of the liver, chronic syphilitic splenitis, and nephritis.

As in other locations, gummas may occur even in congenital syphilis. Splenectomy is advocated by some in persistent syphilitic splenomegaly which resists antisyphilitic treatment when it gives rise to symptoms for mechanical reasons. It is also done in syphilitic cirrhosis of the liver in an effort to reduce the load of blood to the liver, thereby lessening its burden. Splenectomy in syphilis is of little value regardless of the indication.

Syphilis of the Bones, Joints, Bursae, Muscles, and Tendons.—Many medical historians believe syphilis originated in America and was carried back to Spain by the sailors with Columbus. However, there is no doubt that in Biblical times (about 3000 B.C.) the high priests knew and described an affliction with aching bones and joints and a rash. Secondary *syphilis causes a periostitis, a synovitis, and even a transitory arthritis.* In the tertiary stage we may find gummas of bone with irregular areas of destruction. Since syphilitic bone disease is an osteolytic and osteoplastic process, such areas may resemble osteomyelitis (nonspecific) with the formation of sequestra. These may require sequestrectomy. There may also occur osteitis but more often periostitis (saber tibia). The latter is due to an increase in cortical bone limited to the diaphysis on the convex side. The flat bones of the skull may show destruction with se-

Fig. 89.—Syphilitic leucoplakia of the tongue.

Fig. 90.—Syphilis. There is destruction of the nasal cartilages and the hard palate.

due to vascular lesions with resulting degeneration in the tertiary stage. Pathologically there may occur gummatous meningitis, syphilitic arteritis, myelitis, paresis, and tabes dorsalis. There are combinations such as meningoencephalitis, encephalomalacia, or myelomalacia as a result of syphilitic arteritis; meningomyelitis associated with syphilitic myelitis; myelitis together with paresis; and meningitis with tabes. Clinically, the gumma may produce symptoms like a brain tumor (see Chapter 18), which indeed it is. In congenital syphilis the meninges or nervous tissue may have gummas, or due to the surrounding inflammation, the meninges or brain may show edema, meningitis, encephalitis, or myelitis—these too may resemble a brain tumor clinically. Syphilis may cause a neuroretinitis or an atrophy of the optic nerve (primary optic atrophy), producing blindness; it may also cause blindness through *increased intracranial pressure and a choked disc (secondary optic* atrophy). Any of the cranial nerves or groups of nerves may be involved. A panophthalmitis may be due to a diffuse gummatous involvement around the cavernous sinus involving the third, fourth, and fifth cranial nerves (see Chapter 18). *Paresis* causes a "shrinking" in size and weight of the brain as a rule. The white matter may be soft and edematous. The gray matter is hard and there is considerable thinning with much neuroglia proliferation. Cells and tracts degenerate, producing mental changes clinically with "delusions of grandeur." Syphilitic arteritis of the brain begins in the adventitia with miliary gumma formaton or fibrosis. The media (atrophy of muscle) and intima *(thickening) are involved. A "stroke" of paralysis in a young man* (rupture of lenticulostriate artery) is often due to syphilis. *Cerebrospinal syphilis* gives mixed types of paralysis, and tabes dorsalis (locomotor ataxia) affects the dorsal nerve ganglia and posterior horn cells which are degenerated with destruction of the cells and axis cylinders. There is fibrosis in the posterior root ganglia but the cells are not destroyed. The lesion usually begins in the lumbar region, destroying deep muscle sense and producing the typical stamping gait. Often the urinary bladder is involved through its nervous innervation: this is known as *tabetic bladder,* a type of paralysis due to diminished sensation and producing painful urinary symptoms. Surgery is not often indicated in syphilis of the central nervous system. Rarely a subtemporal decompression may be indicated to relieve the increased intracranial pressure, thereby saving the eyesight while antispirochetal therapy is being used. The malaria treatment of paresis in addition to antisyphilitic treatment with penicillin has yielded excellent results. Since malaria and syphilis are protozoan infections it is thought that similar cellular and humoral reactions *are excited. It is a chronic or subacute infection* with an insidious onset; therefore any infection of this type which could be controlled would theoretically be useful in the treatment of paresis (see Chapter 4). The fever itself may help, but it is the number of episodes

questration (craniotabes) and the nasal bones may become necrotic, resulting in performation of the nasal septum. As a result of congenital syphilis children may show a bilateral synovitis (Clutton's joints) or metaphyseal areas of destruction associated with formation of new bone along the shaft; and in tabes dorsalis there may be a *painless* extensive destruction of the knee (Charcot's joints).

Syphilitic bursitis occurs in the tertiary stage. If chronic draining sinuses result with destruction of the bursa, medical treatment may fail; the bursa should be excised under such conditions. Myositis occurs in the secondary stage but it is usually transitory. Occasionally contractures occur. In tertiary syphilis a diffuse interstitial sclerosing process may be found, or there may be gummatous formation with ulceration and fibrosis after healing. Rarely surgery is necessary to relieve contractures.

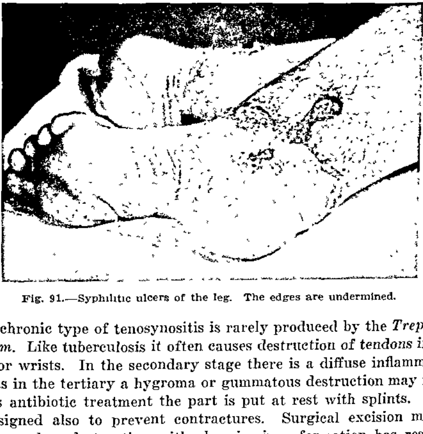

Fig. 91.—Syphilitic ulcers of the leg. The edges are undermined.

A chronic type of tenosynositis is rarely produced by the *Treponema pallidum*. Like tuberculosis it often causes destruction of tendons in both hands or wrists. In the secondary stage there is a diffuse inflammation, whereas in the tertiary a hygroma or gummatous destruction may result. Besides antibiotic treatment the part is put at rest with splints. These are designed also to prevent contractures. Surgical excision may be necessary when destruction with chronic sinus formation has resulted.

Central Nervous System Syphilis.—Some syphilologists believe that a special strain of spirochete is responsible for syphilis of the brain and spinal cord (neurotropic strain). This may be true, but anyone who is afflicted with the disease may have the infection spread to the central nervous system. The syphilitic lesions are the same as in other parts of the body and produce their effects through inflammations of the meninges, glial overgrowths, gummas, fibrosis, and diminished blood supply

fected the wet-nurse. Secondary lesions of the skin and nipple occur *commonly. Gumma of the breast is rare in tertiary syphilis. Surgery* is rarely indicated.

Syphilis in Other Organs.—No tissue or organ is immune. The *testis* is affected in acquired syphilis before the epidymis—this is the reverse of the sequence in tuberculosis. As in other organs, the two lesions that may occur are gumma and diffuse fibrosis. In either there may be sexual impotence. However, this is more often not the case even

Fig. 92.—Congenital syphilis, showing saber tibia.

in the presence of an active lesion. The *treponema pallidum* thus has easy access to the sperm The *pancreas* may be affected in congenital syphilis Here a chronic interstitial pancreatitis with increase of connective tissue results. A diffuse fibrosis occurs in the acquired variety. Pancreatic function may be reduced.

The *thymus* is more often involved in congenital syphilis. Such infants may have the so called Dubois abscesses which are cystlike cavities probably due to softened gummas. The enlarged thymus may produce transient respiratory distress.

of chills and fever and the time element which seem more important than the degree of fever. Artificial heat therapy is not so effective and unless carefully controlled may be harmful to brain cells. Tertian malaria (Plasmodium vivax) is usually induced because it is mildest and most easily controlled. *Other fevers are produced by the injection of typhoid* vaccine, sulfur preparations and non-specific proteins (milk, horse serum).

Syphilis of the Circulatory System.—The heart and blood vessels are always somewhat involved. Syphilitic heart disease (myocarditis, endocarditis, and pericarditis) and aneurysm (chiefly of the aorta but even of other vessels) are not uncommon. Gumma formation does occur in the arteries. More common lesions are syphilitic mesaortitis. The aorta is affected due to an endarteritis of the vasa vasorum which first involves the adventitia, then the media, and, finally, after cicatrization, the intima. The muscular and elastic coats are destroyed and replaced by fibrous tissue which stretches, dilates, and predisposes to aneurysm. In accessible vessels the aneurysm may be obliterated surgically (see Chapter 17). Syphilitic inflammation of the smaller vessels also occurs. This is exemplified in syphilitic arteritis of the brain as previously described. The veins may show periphlebitis, phlebitis, and thrombosis.

Syphilis in Bronchi and Lungs.—Syphilis involves the larynx, trachea, and bronchi in much the same fashion. During the secondary stage transient superficial papules and ulcers occur. The tertiary stage brings gummas which are usually small and flat, often nodular, producing obstruction. The vocal cords may be destroyed by ulceration or rendered functionless by secondary cicatrization. The lungs are more often involved in congenital syphilis. Here there may be one or many gummas in association with pneumonia alba. In acquired syphilis a single large gumma is the most characteristic lesion. It is rare and is usually located in the middle or lower lobe. Fibrosis may extend around the lesion or may be a separate diffuse process. The importance of the lesion is that it resembles tuberculosis or neoplasm clinically and even roentgenologically. Surgery is rarely indicated. But if a large gumma fails to heal under medical treatment, lobectomy may be indicated. This is especially true because of the danger of overlooking carcinoma.

Syphilis of the Uterus, Fallopian Tubes, and Breast.—The cervix is not often affected by the spirochete although, as has been mentioned, chancre (primary stage) condylomas (secondary), and gumma (tertiary) do occur. The uterus is rarely affected; the Fallopian tubes almost never, but there may be gummatous lesions. The breast is also rarely affected. Chancre of the nipple is seen and has been observed bilaterally. Sexual perversion may be a cause of this but more commonly the condition was seen during the era of wet-nursing, when a syphilitic infant often in-

Congenital Syphilis.—". . . visiting the iniquity of the fathers upon the children unto the third and fourth *generation* . . ." (Exodus 20:5) may have referred to congenital syphilis. However, as a matter of fact, it fortunately is not carried to the third generation. It is hoped that the new "hygiene laws" and attempts at eugenics will diminish the incidence of this affliction. Congenital syphilis is not hereditary. It is acquired in utero. Spirochetes are in the placenta. They are also found in semen and some syphilologists believe they may be carried by spermatozoa and may enter the ovum at the time of conception. This is unlikely for the ovum so fertilized would probably not develop or if it did abortion would follow. The syphilitic newborn frequently presents an ugly picture with snuffles (rhinitis), rhagades (fissures about the mouth), mucous patches, and general emaciation, making the "old man" appearance. Routine Wassermann tests of mothers and babies are now done so that treatment may be started early. Treatment of the syphilitic pregnant mother may prevent the transmission of the disease to the fetus. Should the child survive, he may develop one or all of Hutchinson's triad: notched or pegged upper incisor teeth (permanent teeth), eighth nerve deafness, and interstitial keratitis. In addition there may be deformities of the head (prominent parietal bosses), Pitting of the molars, saddle nose, saber tibia, etc. In spite of treatment these stigmas may leave their marks for life.

Summary

Syphilis is a protean disease, mimicking almost every other ailment known. The diagnosis is not always easy. The possibility of this infection must always be considered in any diagnostic problem. The surgeon is sometimes called upon to perform an operation to remove necrotic tissue from bone, to relieve intracranial pressure, to obliterate aneurysms, to correct deformities by plastic surgery, and to release obstructions. Occasionally organs may be so hopelessly destroyed as to demand removal (spleen, testicle). Although necessary surgery is never contraindicated because of the presence of syphilis (except in cases of acute secondary syphilis), medical treatment should always be used to complete the cure. Syphilis per se does not retard repair; however, the poor general health of a syphilitic person may do so.

Syphilis of the tongue may initiate carcinoma. Syphilitic strictures of the rectum and bowel, gummas of the brain, and syphilitic obstruction of the stomach may demand surgical aid.

The prevention of this horrible malady is entirely feasible. A clean, continent life is possible to youth if adequate instruction is given. Wide publicity at present is bringing the entire problem before the adult population. This should be supplemented by correct education, given by the physician himself. Strict quarantine of those afflicted until they are cured will complete the abolition or bring to a minimum the incidence of syphilis.

bears, their constitutional type, their age at death, and the probabilities of one's own future, and even though he be uninterested himself, certainly medicine may know more about the life history of disease.

Due to the complex nature of hereditary factors a pure constitutional type is rare. The average person is a mixture of types. However, in spite of these blends there are three big groups; namely, (1) the linear, slender, asthenic, introvert, hyperevolute, susceptible, leptosome, longitudinal, dolichomorphic; (2) the lateral, broad, hypersthenic, extrovert, hypoevolute, nonsusceptible, pyknic lateral, brachymorphic, plethoric, apopleptic, gouty, round; (3) the intermediate type having some characteristics of each.

Shakespeare knew the two types when he wrote, "Tragedie of Julius Caesar." In Act I, Scene II, Caesar says:

"Let me have men about me that are fat;
Sleek-headed men, and such as sleep o'nights:
Yond Cassius has a lean and hungry look;
He thinks too much: such men are dangerous."

The weave and texture of the cloth of a coat determines its ability to withstand wear and tear, its suitability for fashioning into a garment, its ability to protect its wearer. It is this texture and weave that we wish to examine in defining man's constitution as well as his outward appearance.

INFECTION AND THE HUMAN CONSTITUTION

According to Draper there are four general forces which cause disease. Unless these forces are extreme in their action, they are successfully overcome by the four panels which nature has built into man's constitutional make-up. *Overwork* is combated by the *anatomical* panel; *overeating*, by the *physiological* panel; *overworry*, by the *psychological* panel; and *germs*, by the *immunological* panel. Let us see what is meant by the immunologic panel in man's constitution, and how it combats infection.

It is rare to find a man with four panels equally strong and this difference makes for individual, constitutional types. The mere presence of the meningococcus in the environment does not constitute the disease meningitis. There must first be a conflict—then there is a difference in the reaction of the individual to the meningococcus—A gets the disease and B does not. There has been much work on the meningococcus but not enough on why A is susceptible and B is not; or why two children with the same parents and the same environment differ so markedly in their resistance to disease That is, there may be the same *idiotypic influence* (heredity) and the same *heterotypic influence* (environment), yet the *phenotypes* (the resultant of both influences) are not the same, in so far as their immunologic panel is concerned. To use the vernacular, one child "gets everything that comes along, but the other is as tough as leather." How

PART III

GENERAL REACTIONS TO INJURY

Chapter 10

THE HUMAN CONSTITUTION

In previous chapters we have observed the body's reactions to mechanical injury and bacterial trauma and its behavior in miscellaneous infections, tuberculosis, and syphilis. In this chapter we shall try to account for differences in reactions to injury and disease and for the probable endogenous factors which may be responsible for certain ailments. In so doing we should begin with a consideration of the human constitution, including its hereditary and environmental origin. This should enable us to understand in a better way the source of compensatory mechanisms which come into play in response to injuries of all kinds, including those of unknown origin (neoplasia), as well as to those abnormal states brought about by disturbances in acid-base balance and water balance and those due to hemorrhage and shock. These subjects are discussed in following chapters. However, it should be mentioned here that these compensatory mechanisms are constantly at work. They are ample to care for ordinary physiological, immunologic, or psychological abnormalities and they usually respond without discernible symptoms and signs. It is only when ordinary reactions fail to restore normalcy that nature resorts to more drastic reactions in an effort to save life. Here certain syndromes are noted such as shock, acidosis, alkalosis, dehydration, etc.

In fact, it is the strength of compensatory mechanisms which prevent what we ordinarily call sickness. In a broad sense the clinical symptoms and signs of sickness are due to the fact that ordinary "reserves" are unable to cope with an injury, whether it be bacterial, chemical, thermal, or other kinds. If these resistance factors were strong, nature would not resort to extreme prostration or high fever, etc., to meet the issue. Sickness, then, in a clinical sense is a group of symptoms and signs which are a part of these compensatory mechanisms stimulated to a degree which makes them evident.

Some believe that a discussion of the human constitution is abstruse, indefinable, and academic. Others aver that classification of constitutional types and their heredity may lead to a more accurate understanding of disease, its origin, and prevention. Indeed by going to the health department file one may look up the cause of death of his fore-

serious illness, such as empyema, typhoid, spreading peritonitis, etc. Within a few years they are obese and remain so. Racial resistance to certain organisms is peculiar to definite constitutions: certain reactions to disease may be inherited through generations as actual constitutional qualities. This tendency is seen in allergic states. The formation of polypoid hyperplasia in the paranasal sinuses is directly attributable to protein sensitization. The infection that usually supervenes is entirely secondary and is probably caused by an interference with proper drainage. Many examples of racial immunity are known, such as the apparent freedom of the Negro from yellow fever, as opposed to his susceptibility to tuberculosis.

In evaluating this state called immunity, we are struck with the maze of conflicting evidence as to how immunity occurs. Immunity to certain virus diseases is said by some to be due to maturation of the individual; by others, to the individual's having contracted the disease in a subclinical form upon his initial exposure to it. Immunity to any disease may be natural or acquired, relative or absolute, local, general, or both local and general. Absolute immunity is uncommon in man. On the other hand, man usually has some immunity to all diseases, with the possible exception of glanders. In lower animals there seems to be an absolute immunity to leprosy.

There is increasing evidence of the transmissibility to man of diseases peculiar to lower animals (for example, undulant fever, tularemia, rabies, etc.). The reverse seems to be true also.

Our immunity is necessarily relative and depends upon the virulence, number, and kind of bacteria as against the state of health, local resistance, and constitutional type of the individual.

Some investigators now believe that every tissue in the body has cells which may become phagocytic under proper stimulation. When dyestuffs such as trypan blue are injected into animals, granules appear in macrophage cells everywhere. In rats the skin and mucous membranes remained blue for three months. Niemann made an incision in such animals and sewed a small gauze sponge under the skin. Nine days later the dye had colored the sponge, and the skin and mucus membranes began to lose their color. This means that the reticulo endothelial cells were transported to the site of the infection (see Chapters 4 and 5). The "blocking" of the reticulo-endothelial system was thus cleared, and its functional activity was increased. Infections which terminate favorably may in this way stimulate the functional activity of the reticulo-endothelial system. Menken showed that trypan blue, when injected intravenously, accumulates in the tissue of an inflamed area. The same is true of bacteria. This suggests that the well known tendency of infection to occur in a place of lowered resistance is due to an increased permeability of the capillaries (see Chapters 4 and 5). Perhaps, too, this explains the phenomenon of Arthus and Shwartzman (that is, when a bacterial toxin is injected into the animal intravenously, there occur violent local inflammation and sloughing).

The normal individual is one who meets and conquers the ordinary adverse forces in nature. Immunity seems to be due to cellular phago-

can we tell the A type from the B type—the asthenic, linear, introverted, hyperevolute and susceptible type from the pyknic, lateral, extroverted, hypoevolute and nonsusceptible type? Morphological, physiological, and psychological studies will help us. Moreover certain immunologic tests help to determine types. Examples of such tests are skin reactions to protein, metabolism tests, the Dick test for susceptibility to scarlet fever, the von Pirquet and Mantoux tests for tuberculosis, the Schick test for susceptibility to diphtheria, etc. The susceptibility of a child of the linear type to infections such as tuberculosis, rheumatic fever, and diphtheria is pointed out by Hurst and others and is a common observation.

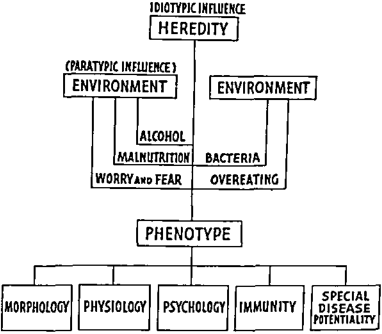

Fig. 93.—Diagram illustrating Draper's theory of phenotype. The idiotypic influence (heredity) is perhaps stronger than the paratypic (environment). Both produce the completed product (phenotype), whose constitution is divided into four panels and a special disease potentiality. (Redrawn from Draper.)

What is immunity? The dictionary defines it as "a state, natural or acquired, in which the body is resistant to disease." Stockard has said, "The same disease-causing organism does not produce the same effect on all personalities. These differences are not all due to differences in the constitutional quality of the individual persons attacked." *Immunity may be said to represent the changes in the constitutional state produced by germs.* These changes (called *immunity*), or the processes by which they are acquired, may in themselves set up constitutional states which modify or deviate to some extent the further growth and developmental qualities of the individual. The immunologic panel is therefore a varying part of each individual type of constitution—but, because of its modifying influence, it may be the *cause* of a particular constitutional type. We have all observed children of the so-called linear type recover from a

door." And conversely, the mere presence of an inflamed area does not constitute an infection or a general septicemia. Draining an abscess does not cure an infection; it aids the forces of immunity (which caused the infection to localize). We are apt to say that our particular type of antiseptic, antibiotic, or chemotherapeutic agent or method of treatment *cures* and to forget the patient in the equation. We have shown that granulations in a surgical wound after the sixth day are immune to staphylococci rubbed on them, and this observation, no doubt, applies to man as well as animals.

Infection and resistance may truly be compared to a fight. It is not guerrilla warfare with a haphazard defense by ill-trained and inexperienced troops. It is, in those individuals with a high degree of immunity, a well-organized and systematic defense, the details of which we may clearly observe in the superficial abscess.

It is the degree of organization and ability of the soldiers of the reticulo-endothelial system to fight that determines whether a given pnenotype which heredity and environment may produce has a strong or weak immunologic panel. Even the streptococcus, which fights from ambush as a sniper, does not take the strong constitutional type by surprise. His warriors have come down to him from his ancestors, well fitted to cope with these enemies. This, indeed, has made it possible for man to survive. Potential enemies of this sort exist in many tissues of the body at all times. There are probably small areas of infection and inflammation continually present in various parts of the body. These areas have been called chronic, symptomless, silent foci of infection. In view of present concepts, we may conclude that the individual with a good immunologic panel is well able to cope with such areas of germ life. His forces of resistance are acquainted with these indigenous bacteria and, if not interfered with, will destroy them completely, wall them in, or keep them harmless. To try to eradicate all of them would obviously be impossible, and, in the light of present knowledge, entirely unnecessary.

Applying our discussion in a practical manner, we may say that the *constitutionally strong survive the ever-present bacteria, and that in those not so strong it is far easier to build up the immunologic panel than to attempt the eradication of every potential area of infection of endogenous or exogenous source.* Every other panel is directly associated with the immunological. Anatomical (strong physical bodies), physiological (proper food), psychological (happy, wholesome outlook, psychosomatic factors)—each, in turn, helps the other. Since the advent of chemotherapy and antibiotics we are more than ever aware that *an infection is* overcome by body resistance. The drugs simply retard bacterial growth; their ultimate destruction is due to local and general immunity as previously defined. (See Chapters 4 and 5.)

cytic action and to humoral effort. Local immunity is the result of phagocytosis by a large group of mesenchymal cells, such as the heterophile leucocytes, the fibroblasts, the monocular exudate cells, the polyblasts or histiocytes, and the pericytes. A local humoral, immune substance (whose nature is unknown) has also been thought by some to aid in local immunity. General immunity is the result of both humoral and cellular forces. The latter are included in the great group of phagocytic cells known as the reticulo-endothelial system. It has been found in the experimental animal (see Chapter 4) that in staphylococcic septicemia trypan blue will not appear at a superficial site of local injury. This is due to peripheral vasoconstriction. The reticulo-endothelial cells and polymorphonuclear leucocytes are being used in more vital central areas. This explains why local immunity and fibroplasia are retarded in the presence of a septicemia.

The blood cells, such as polymorphonuclear and mononuclear leucocytes, and that group of general immune substances known as antibodies, and designated variously as agglutinins, bacteriolysins, precipitins, alexins, antitoxins, and opsonins, constitute the humoral forces that are available for effecting a general immunity to disease.

Explants from the spleen, the lungs, or the bone marrow of embryonic or adult laboratory animals are incapable of synthesizing precipitins, agglutinins, hemolysins, antitoxins, or complement-deviating antibodies. If antigens are injected into the living animal and an interval of two to three days allowed, then antibodies of high titer may be found in various organs. This tends to prove that *antibody production is the result of preparatory reactions produced by the body as a whole.*

Mackay and Menkin and others have shown that insufficient amounts of vitamins A and C may decrease the immunological panel.

In all probability these different types of immunity are very closely related and respond synergistically when needed. However, we have ample proof that local immunity can take care of a great many infections unaided (see Chapters 4 and 5). We may summarize by saying that this constitutional state broadly termed immunity is the sum total of the factors just mentioned. These are the actual scientific units in the immunologic panel. Why one person has an active well-trained reticulo-endothelial and antibody system and another an ill-trained, inactive one, we do not know. How to know which person has and which has not can be partially determined by panel types, various skin and serological tests, and blood counts, which we have described in previous chapters.

In infections that are localized, the very fact that they have localized and have not overwhelmed the patient bears evidence of good resistance. *Inflammation* due to pathogenic bacteria and *immunity,* whether local or general, are not the same thing. If we could artificially wall in an infected area by an inflammatory zone, it would not necessarily cure the patient or prevent a general septicemia or the occurrence of other infections "next

assortment as well as other generalizations. He found, for example, that *by crossing a pure red-flowered with a pure white-flowered pea plant* that the red-flowered plant appeared—no pinks or whites. Yet in subsequent generations white appeared. Thus he spoke of redness as dominant and whiteness as recessive. If the red offspring was self-fertilized, the resulting generation would be three-fourths red and one-fourth white. *If now there is an absence of dominance in the offspring between red* and white, that is, pink, then after self-fertilization in this flower the next generation will be one-fourth red, one-half pink, and one-fourth white. The unit characters have been separated and redistributed. This is known as the principle of segregation. As in plants, so in man, the in*dividual is an aggregation of more or less independent and separable* "unit characters," each of which is distinct and may exist in all sorts of combinations. Moreover, these traits exist in hybrids as contrasts: red and white, tall and short, etc. Such pairs of characters are called *allelic* pairs, one being the allele of the other. This is well exemplified in *the heredity of blood groups which we shall discuss later.* The principle of independent assortment assumes that "the relation of each pair of different characters in hybrid union is independent of the other differences in the two original parental stocks." Sinnott and Dunn have used the following example:

> Assume that of all the men in a given country half are brown-eyed and half are blue-eyed and that half are right-handed and half are left-handed. Assume further that there is no connection between these two characters so that of the brown eyed men approximately half are right-handed and *half* are left-handed, and of the blue eyed ones, the same. There will thus be four kinds of male individuals in about equal numbers. . . . Finally assume that the women are divided in just the same way and that *in determining what matings shall take place between men and women, eye color and* right-handedness and left-handedness play no part whatever. . . . The existence of four types of men and four types of women in about equal numbers will then result in 16 kinds of matings, although as far as actual appearance goes, there will be only four kinds of individuals. Therefore, the *genotype* (the germinal make-up of the individual; *the basic complex of genes) is not always apparent by outward appearance.* The *phenotype* as we have seen is the individual resulting from the interreaction of the parental genes; his appearance depends on dominant factors but he still harbors recessive factors as well.

HEREDITY IN BLOOD GROUPS

We are familiar with the blood groups, O, A, B, and AB—these are phenotypes. Due to the fact that certain genes are dominant over others, any given phenotype may be the expression of one or more genotypic pattern. In blood groups there are three allelic genes: A, a^B, and a. The first two (A and a^B) are dominant over the third (a) but are not dominant over each other. The gene A is responsible for the blood group A, a^B for group B, *a for group O, while the presence of both genes A and* a^B produce group AB.

This is the philosophy that governs the physician in his treatment of infection. It may sound like therapeutic nihilism; actually, it is simply the application of sound medical and surgical principles when infection occurs. It is a revival of Jonathan Hutchinson's dictum: "It is more important to know the patient than his disease." Consideration of the patient as a whole is necessary for successful care and cure.

HEREDITY AND THE HUMAN CONSTITUTION

Individuals tend to resemble their ancestors closely; this resemblance is called *heredity*. When the sperm units with the ovum (gametes) to form one fertilized cell (zygote), a new individual develops. In the elements of these cells reside the potential characters of the offspring. The anatomical pattern (color, eyes, skin, hair, size, shape, and body proportions), immunological pattern (susceptibility to defects and disease), physiological pattern (chemical peculiarities of blood and tissues), and psychological pattern (mental traits and capacities) are all inherited. True enough, variations occur. Practically no two individuals are exactly alike even though their resemblance is extremely close in every way. The science of genetics is a study of the phenomena of inheritance and variations. It attempts to formulate laws which govern similarities and differences between people related to one another by descent.

Variations occur in some panels because of environment. This is especially true in the psychological behavior of an individual. However, acquired characteristics are not transmitted as such.

Acquired characteristics are not transmitted, notwithstanding Lamarck's doctrines. An acquired character is one that has developed in the course of the life of an individual in the somatic or body cells, usually as a direct response to some external change in the environment or through the use or disuse of a part. Therefore, acquired immunity is not hereditary. Is it, then, the inheritance of a particular type (lateral) which affords a strong immunological panel? While this is true in general, the fact remains that certain races (composed of both linear and lateral types) have a strong immunity against certain diseases. Perhaps this may be explained by the modern conception of Darwin's pangenesis; namely, that the units of heredity already present may be modified by late contributions from other parts of the body and such modifications may be inherited.

Occasionally an individual will be found who differs greatly from his forebears for reasons as yet unknown. He is not only different himself, but he transmits his differences to his descendants. Such a new variation is known as *mutation* and is observed not infrequently in animals and plants as well as man.

Mendel's laws of inheritance were formulated by counting the numbers of each type of progeny resulting from a given cross and furthermore each trait or *character* of the pairs and their offspring. He was able thereby to formulate the principles of *segregation* and *independent*

In cases of disputed paternity it is not possible to say definitely that a child is the offspring of certain parents, but in some cases it is possible to affirm that the child is not their offspring.

HEREDITY IN CONGENITAL MALFORMATIONS

It is perhaps erroneous to assume that all congenital malformations and deformities are hereditary. Some are definitely so and may behave as dominant or recessive. Among the former may be mentioned telangiectasis and hypospadias and among the latter a score of abnormalities including albinism, harelip, certain types of blindness, anomalies of the gastrointestinal tract, etc. As is well known, hereditary traits are determined by genes carried in the chromosomes of the nucleus. Every individual receives two of every type of gene—one from each parent. In a simple dominant condition if one gene is defective it will appear on an average of one of every two offspring. In a simple recessive condition a pair of the same genes is required for the defect to show up in the individual. If the child receives a defective recessive gene from one parent, he will be normal but will be a carrier. If two carriers who are normal mate, a defective child will appear one in four times. If a defective parent and a carrier mate, the defects will appear once in two times. If both parents are recessive defectives, all children will be defective.

Sonneborn has shown that in the paramecium there may be a very different genetic system: the hereditary traits may be determined by nuclear genes in some of the species but in others they may be determined by the cytoplasm. He called these cytoplasmic factors *plasmagenes* because like genes they are self-reproducing and control the characteristics but unlike the genes they are located in the cytoplasm instead of the nucleus. They are, however, partly dependent for their maintenance and reproduction on the nuclear genes. Just what role these *plasmagenes* play in human heredity has not been determined. Perhaps chemical, virus, and other carcinogens induce mutations in plasmagenes which are more readily affected. The long period that normally intervenes between the application of carcinogenic agents and the visible development of cancer in experimental animals may be due to the fact that during this period the cellular concentration of the plasmagene is slowly increasing up to the critical level for cancer manifestation.

Murphy has made an exhaustive study of the incidence of congenital malformations in families. He believes that these arise from influences which affect the germ cells prior to fertilization. Other observations were: about one-fourth congenitally malformed are stillbirths, they are twice as common in whites as in Negroes, they are twenty-five times greater in families already having a malformed child. The older mother, the later-born rather than the first-born, long periods of sterility, all point to the occurrence of defects.

Since two genes, one contributed by each parent, interreact to produce the phenotype, Table VIII shows the genetic constitution responsible for any one of the four blood groups:

TABLE VIII

PHENOTYPE (BLOOD GROUP)	GENOTYPE

pagos, joined) indicates a union ventrally of the chest and belly. This may imply a communication between thoracic and abdominal cavities with a single organ or double organs supplying the monster (*monere*, to warn; or *monstrare*, to indicate).

The modern theories of the cause of monsters and anomalies are described as developmental inhibition or arrest. Each organ not only originates from a definite embryonic area or primordium and from no other, but also it arises at a definite moment that must be utilized then if ever. Also if one organ is out of time others also are thrown out. Interference with the fetus in any way (ectopic, radiation, oxygen deficiency, lowering of temperature, slow rate of development) may produce anomalies.

Older theories included such intrinsic factors as vitality difference, fetal disease (local necrosis, improper physiological regulation), and interdependence of fetuses. Extrinsic factors were listed as direct (mechanical, physical, chemical, or transmitted disease) and indirect (environmental influences).

The role of heredity in anomalies is not entirely settled. Yet the occurrence of twinning and monsters in family lines transmitted equally often through the male or female makes the hereditary factor a very important one.

HEREDITY AND DISEASE

Many diseases appear in successive generations of a family: gallstones, goiter, varicose veins, hernia, appendicitis, hypertension, coronary disease, myopia, allergic diseases, hemolytic jaundice, peptic ulcer, "congenital" hypertrophic pyloric stenosis. and, above all, cancer. A familial incidence does not prove that a condition is hereditary nor does its absence prove that it is not. However, the knowledge that many *diseases are hereditary and moreover the potentialities of such diseases* are of great importance.

Some diseases are hereditary and behave as dominants (Huntington's chorea, paralysis, agitans, labyrinthine deafness, etc.). Some are recessive (diabetes mellitus, amaurotic idiocy, spastic paralysis, etc.), Some are sex-linked (hemophilia, color blindness, juvenile glaucoma).

The gene for hemophilia arises about once in 10,000 times in men and about once in 100,000 times in women. The usual sequence, then, is a mutation in the germinal tract of a man, whereby he has a carrier *daughter, the disease itself appearing when her son is born.* The fertility of affected males is less than one-third of the normal rate, so that genes for the condition are fairly well eliminated. Mutation and elimination balance each other so that the population is in equilibrium, with about 1 boy in every 7,500 boys being born a hemophiliac in Denmark. Andreassen demonstrated a delayed coagulation time in carrier women. This test can be used to assure the 50 per cent of the sisters of hemo-

Teratology (terato-logy, a telling of wonders) is the study of embryology that deals with abnormal development and its products; namely, anomalies. Normal individuals vary greatly from others of the same species as a whole and as to individual organs or parts. Great variations may occur in one individual or in twins. Twinning is in itself abnormal. Malformations are listed by Arey as follows:

1. Developmental Failure. The primordium may fail to appear or at least not develop to a significant degree. This is known as *agenesis*. Examples: absence of an arm or kidney.
2. Developmental Arrest. A transitory fetal state is retained permanently (cleft palate, imperforate anus, double uterus).
3. Developmental Excess. Growth is exaggerated or normal numbers are increased (gigantism, accessory digits, or mammae).
4. Displacement. Organs whether typical or supernumerary may occupy abnormal locations (transposed viscera, palatine teeth).
5. Fusion or Splitting. (Horseshoe kidney, cleft ureter.)

TWINS

If there is an independent fertilization and ripening of more than one ovum at a time, *ordinary* or *fraternal* twins are produced. They may be of the same sex or mixed and are not really twins. They resemble each other as do other brothers or sisters. When a single ovum develops into two or more individuals, they will be of the same sex and will have similar physical, mental, and pathological traits because each member acquires the same chromosomal heritage and therefore the same genetic constitution. These twins are known as *identical* or *duplicate*.

In single-ovum twins one individual may be normal in size and structure and the other less so or completely unable to exist as an individual after birth. Rarely they may be joined (double monster) by a small area of fusion or the entire bodies may be fused except the head or legs may be double. The former type (superficial union) may be separated surgically. When vital organs are divided both individuals may die or one may survive at the expense of the other—rarely both survive such procedure.

In otherwise normal persons one half may be larger than the other. This may be interpreted as a twin specimen with a minimal degree of doubling (Arey).

If there is a difference in size of the two components, the larger is called the *autosite*, the smaller the *parasite*. If the parasite is a perfectly included twin it is known as fetus in fetu. This is mentioned in Chapter 15 under teratoma, a tumor which includes parts of organs or almost the entire *parasite* within its capsule. Although the term *dipygus parasiticus* is often used to describe conjoined twins of different size, it is perhaps better to limit its use to those joined at the pelvis or lower part of the back (*dipygus*, double buttocks). Other terms are used when junctions are present elsewhere. *Gastrothoracopagus* (*gaster*, belly; *thorax*, chest;

abdominal cancers in kangri users; third, those due to medicinal agents (x-ray and radium and arsenic); fourth, those induced by chemicals in *occupations (arsenic, nickel, carbonyl, radium, mesothorium, asbestos,* mineral oils, pitch, tar, soot, paraffin oil, anthracene oil, creosote, aniline, naphthylamine, benzidine, benzene, all radioactive materials); fifth, a special miscellaneous group induced by parasites and virus. Internal and environmental factors include hormones, endocrine abnormalities, endocrine traits, inherited precancerous conditions such as necrofibromatosis, tuberous sclerosis, intestinal polyposis, xeroderma pigmentosis, and inherited metabolic abnormalities (hematoporphyrinuria from the sun makes skin more susceptible to tumors and it is itself a constitutional anomaly caused by light).

If there is a general susceptibility and an inherited favorable internal environment or if external environmental factors are present, such an individual may be a subject for cancer. In the latter instance the environmental factors may induce a predisposition to cancer. This subject will be discussed again in Chapter 15. The constitutional factors involved in cancer are varied and as yet not entirely known. However, here, as in infections, it takes two factors to produce the disease, the soil and the seed. Unlike infections, we know little concerning the seed (cause) and only a fragment more about the soil (resistance).

philiacs who have not received the gene that they are not carriers and so can safely marry and have children, although its reliability cannot be considered as infallible.

In a large proportion of mental diseases and in diabetes mellitus, for example, environment plays a role as important as does heredity. In some instances the hereditary factor is known; for example, congenital polyposis of the colon. Its tendency to become malignant is also known. Therefore, here colectomy is definitely indicated as soon as the condition is discovered. Moreover, if it is found in one member of the family, it should be sought and eradicated in other members if present. The same may be said for retinoblastoma.

Cancer may be the result of heredity or environment or both. Undoubtedly cancer is not a unit disease so far as its *genetic behavior* is concerned. Tumors of different sites and types may show a strong hereditary factor or one in which it is possible but not sure, or there may be no suggestion of a hereditary factor at all. A high incidence of cancer in a family or families does not constitute statistical evidence for the heritability of cancer because of the frequency (one of every ten deaths) of the disease. By the law of probability it is bound to occur in a certain number of families and in twins. However, its occurrence in many such families and twins has been reported so commonly that it is certainly more than a coincidence, indicating the importance of heredity in the formation and localization of certain tumors, such as those of the colon, eye, breast and stomach.

Much research has been done on the genetics of cancer in animals. These studies include modes of transmission (species difference, general predisposition, localization, mendelian mechanism) and extrachromosomal (cytoplasmic) and milk-borne factors (in cancer of the breast). Since milk is the product of a portion of the cell's cytoplasm (apocrine gland, Chapter 22), perhaps the milk-borne factor is the plasmagene as described by Sonneborn.

There is much difference of opinion concerning the genetic behavior of cancer in animals. Slye believes that susceptibility and insusceptibility to cancer are unit characters involving one gene and that susceptibility behaves as a recessive and unsusceptibility as a dominant.

It is unlikely that a heritable spontaneous "cancer" condition exists in many and very improbably that one gene, dominant or recessive, is responsible for it if it does exist (Haldane).

It is better to speak of "inherited disposition" whether of refractoriness or susceptibility to tumor formation.

Environment, external and internal, plays an important role in susceptibilities. In the former group may be mentioned, first, those factors natural in the environment (arsenic in drinking water), solar cancers in dry sunny regions, bladder cancers in tropical regions where schistosomiasis is endemic; second, those due to habits (smoking, tobacco chewing,

Chapter 11

THE INTERCHANGE OF BODY FLUIDS

Approximately 55 per cent of the blood volume is made up of plasma and 45 per cent is made up of cells. The blood circulates within the vascular system in what might be termed three types of vessels: the large arteries and veins (vessels of storage), medium arterioles and venules (vessels for distribution), and the smal capillaries (vessels for interchange of oxygen, food, and waste products). Of the three types the capillaries are all important in the regulation of water balance. The capillaries are made of a single layer of endothelial cells, about 0.8 micron thick (less when dilated) and permit an exchange of food, water, electrolytes, oxygen, carbon dioxide, waste products, etc. However, this free passage through the capillary wall is possible only to crystalloids (inorganic salts, glucose, etc.) which are in true solution (solutes) in blood plasma; it is less possible to colloids (of which the most important are the solute proteins: serum albumin, serum globulin, and fibrinogen, totaling 6 to 8 Gm. per 100 c.c. of blood) because to these substances the capillary wall is normally impermeable, especially in the periphery of the body where plasma volume maintenance occurs. In the central viscera (lungs, liver, and visceral lymph) capillaries are almost as permeable to serum albumin as to crystalloids so that about half of the serum albumin is in the interstitial spaces. These colloids and crystalloids constitute a pulling force, which if unopposed would drain the intercellular fluid into the capillaries. However, it is offset by the hydrostatic pressure within the capillaries which constantly exerts an outward force. Therefore, the fluid within the capillaries is between two forces: the osmotic or "pulling" force and the hydrostatic or "pushing" force (Starling's theory). The same forces also affect the movement of the intercellular fluid and, to a lesser extent, of intracellular fluid.

The fluid structure of the body consists of three parts: the blood, the intracellular fluid, and the interstitial fluid, the sum of which constitutes about 70 per cent of body weight. This is divided as follows: the volume of circulating blood plasma is approximately 5 per cent, interstitial fluid comprises about 15 per cent, and intracellular fluid about 50 per cent of body weight. The interstitial fluid which includes the lymphatics is the most labile of the three, for in order to preserve contact with the other two it must undergo a constant shift in amount and, to a less extent, in electrolyte content.

Since on the arterial side of the capillary loop the hydrostatic force is greater than the osmotic, there is a passage of fluid outward into the

the ameba, has a porous wall and therefore can absorb particulate matter. Blood cells, in general, are easily affected by their environment: hypertonic solutions produce crenation; hypotonic solutions, swelling. Cells in the mucous membrane of the bowel and in the tubules of the kidney have a selective action: in the intestine these cells may refuse or select protein; in the kidney, water and glucose are reabsorbed. Therefore, the cell, while dependent upon the intercellular fluid and oxygen for its survival, is not governed entirely by the mechanical principles advanced under Starling's theory—it has in addition a *vital selective and secretory power*. The water content of the cell is mostly *free*, that is, not *bound* by colloids, and is given up easily when needed.

DIAGRAM SHOWING THE MOVEMENT OF WATER BETWEEN BLOOD AND TISSUES*

	BLOOD ARTERIAL SIDE	TISSUE FLUID	BLOOD VENOUS SIDE

Fig. 95.

Osmosis, Oncotic Pressure, Dialysis.—The osmotic pressure may be defined as the attracting force exerted by crystalloids and colloids in the capillaries. The actual pressure developed is supposed to result from the bombardment of the walls of the capillaries by imprisoned molecules of the dissolved or suspended substances. The permeability or semipermeability of the capillary wall is an essential factor in the development of the osmotic pressure. Since the capillary wall is normally less permeable to colloids, these substances exert a sustained osmotic pressure. The oncotic pressure is the osmotic pressure of colloids. Crystalloids, on the other hand, pass through the capillary wall readily and therefore they can exert an osmotic pressure only temporarily when a sudden change in concentration of these substances is introduced within the lumen of the capillary. The behavior of the tissue cells as has been stated is also affected by this process of osmosis. For example, the red blood cells are impermeable to potassium, sodium, and calcium, but they are permeable to water, chlorides, and bicarbonates. This will be discussed in the next chapter when we study the chloride shift.

tissue spaces. By the time the blood has reached the venous side of the loop, the hydrostatic force has fallen and the osmotic force has slightly increased (due to loss of water from the blood) and therefore the flow is from the tissues toward the vessels. Apparently the entire mechanism is a mechanical one and does not involve any selective action on the part of the vessel wall. The interchange of fluids is quantitatively expressed in the accompanying diagram.

In Chapter 17 we shall learn that lymph is composed of the intercellular fluid with some cells and particulate matter. Tissue fluid is forced into the permeable lymph vessels entirely by the hydrostatic force in the tissue spaces and the lymph vessels carry back to the blood stream such proteins as are not readily absorbed by the cells. The passage of water in and out of tissue spaces is probably intermittent. The spaces are artifacts; there are no lacunae in the tissues and no brownian movement has been observed (Freeman).

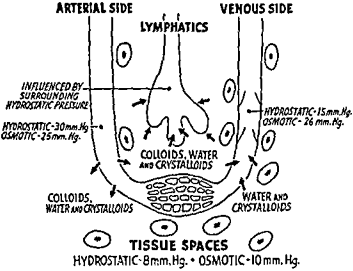

Fig. 94.—Diagram illustrating Starling's theory of the interchange of fluids. The effective hydrostatic pressure on the arterial side of the capillaries is 7 mm. of Hg; therefore fluid goes out into the tissue spaces. The hydrostatic pressure is reduced on the venous side and the osmotic pressure is increased because the blood has been concentrated by loss of fluid. The effective osmotic pressure is about 9 mm. of Hg, and water and crystalloids are absorbed. The permeable lymphatics absorb colloids as well as crystalloids and are influenced by the tissue-space hydrostatic pressure (muscular contraction, arterial pulsation, motion) although their colloid content exerts a small osmotic pull as well. The diagram represents a capillary loop and small collaterals.

The last and most important fact to be considered is the behavior of the intracellular fluid. Of this, little is definitely known. However, we do know that it varies with the type of cell. In unicellular organisms a single cell carries on all the functions necessary to the life of the animal. In higher animals different groups of cells have different functions. All cells are affected by their environment (tissue fluids and oxygen) and respond more or less to alterations in this environment. The mechanism by which they absorb foodstuffs is probably dialysis. The cell assimilates single molecules and synthesizes them into the complex substances which constitute its protoplasm. The macrophage, like

blood plasma. Plasma proteins are lost continually in varying amounts but are returned to the blood by the lymphatics. Capillaries are constantly being traumatized and repaired in part by the circulating fibrinogen which is converted into fibrin.

Within the capillaries are the red blood cells with a total surface of 30,000 square feet or nearly 3/4 acre. The great area of filtration which the capillaries possess is not easily described. Their permeability is such that the entire plasma volume could be filtered within ten seconds at a capillary pressure of 10 mm. were it not for the vasomotor action and the osmotic pull within them and the tissue space pressure around them. Capillary permeability is increased by many factors, it is decreased by none according to Krogh. However, he admits the possibility in citing Isayama's work on the loss of fluid from the frog's blood. After trauma by the cautery to the lymph hearts there is a latent period of six minutes before fluid loss begins. If fluid is lost between the endothelial cells more easily when they are separated, then a priori they should be lost less easily when approximated. The following is a list of some of the factors influencing capillary *permeability:*

A. Increased
   1. Inflammation
   2. Prolonged application of heat
   3. Anoxia
   4. Scurvy (vitamin C deficiency)
   5. Trauma
   6. Capillary poisons
   7. Allergy
   8. Vasodilation from nervous or other factors

B. Decreased
   1. Vasoconstriction

Osmotic Pressure Within the Capillaries.—The osmotic pressure of a solution of any pure substance depends upon the number of molecules, ions, or other particles which are present, irrespective of their kind or size. The osmotic pressure of a solution containing a mixture of substances is made up of the partial pressures of the single substances; that is, each substance acts as if it were alone, unless its free particles are modified by the presence of the others. The osmotic pressure of the blood is due mostly to inorganic salts and organic materials dissolved in the plasma. Starling showed that the proteins, which make up practically the whole of the colloids, have a definite though small osmotic pressure. The *osmotic pressure of the crystalloids cannot be continuously effective in normal capillaries because their walls are permeable to these substances. The osmotic pressure of the colloids is effective because of the relative impermeability of the capillaries to them.*

Probably the three proteins do not exist in the blood as separate and distinct substances but are bound together into a single complete substance, which is disrupted into its constituents by different agencies. Serum albumin amounts to 4.4 grams per 100 c.c. Its osmotic pressure is 5.5 mm. per gram or 24.2 mm. The albumin fraction contributes 85 per cent of colloidal osmotic pressure (1) because its molecular weight is the smallest and (2) because its concentration is twice that of globulin. The pressure which each protein fraction exerts is inversely related to its concentration in the plasma. Serum albumin is in the highest concentration and its molecule has the least

The term dialysis implies the separation of crystalloids and colloids in solution by means of *their unequal diffusion* through a natural or artificial membrane. Plasma exerts an osmotic pressure of about 25 mm. of mercury against a semipermeable membrane with isotonic salt solution on the outside. Five millimeters of this pressure difference are due to the unequal distribution of electrolytes in accordance with Donnan's law, which is discussed later in the chapter, and 20 mm. of mercury are due to plasma proteins. Serum is chiefly defibrinated plasma and *therefore it contains albumin and globulin but no fibrinogen.*

Colloids, Crystalloids.—The word colloid is derived from the Greek meaning glue and was originally introduced by Thomas Graham. He divided all substances into two classes; namely, *crystalloids,* including such substances as salt, sugar, urea which could be crystallized with ease, which diffused rapidly through water, and were capable of diffusing through dead animal membranes, and *colloids,* which included substances such as gelatin, gum, egg albumin, starch, dextrin, which were noncrystallizable, formed gummy masses when their solutions were evaporated to dryness, which *diffused with extreme slowness* through water and would not pass through animal membranes. At present these criteria do not hold, because *proteins can be obtained in crystalline form and different* colloids have different gradients of diffusion. Colloids exist under two *conditions:* (1) in a state of solution or *pseudosolution in which they* form sols and are designated as hydrosols when the solvent is water; (2) in a solid state in which a relatively small amount of the colloid sets with a large amount of fluid, such as water to form a jelly. This solid form, that is, gelatin, is known as a *gel.* Such a watery jelly is known as a hydrogel.

The Capillaries.—The capillaries form an enormous filtering area which is said to be 6,800 square feet or a thin membrane one yard wide and four miles long. Their total length is about 100,000 miles. The capillary walls are so thin that it would take about 30,000 to make an inch. They are a continuous tube branching repeatedly and being exposed directly to the tissue fluids, oxygen, and carbon dioxide. In the normal person they are continually dilating or contracting to diminish *or increase the supply of blood.* Hydrostatic pressures within the capillaries change some but osmotic pressure varies only slightly and *temporarily under normal conditions.* There is *great* variation in capillary permeability in different parts of the body.

The pleural capillaries are *most permeable, then the peritoneal,* then the cerebrospinal, and the least permeable are the subcutaneous. This same variation occurs in *different organs; the liver* where capillary endothelium is partly discontinuous loses most protein, the kidneys less than half as much. *Obviously interstitial fluid will vary in protein content* in these regions, that of subcutaneous tissues being 0.1 per cent protein, the kidneys, 3 per cent, and *the* liver, 7 per cent, or *equaling*

is best supplied by animal proteins, although their ingestion does not result in an immediate increase in plasma proteins which must first be synthesized by the liver. In disease the reserve supply is the principal source. This is important because a patient may have normal plasma protein fractions with the reserves exhausted. After surgery when protein is needed there is nothing to draw upon and hypoproteinemia results. The body can synthesize all amino acids into protein, but it cannot form amino acids except glutamic, alanine, and arginine.

Some of the so-called nonessential amino acids are provided by the synthetic action of bacteria in the large intestine. This is also true of the synthesis of vitamin K_2. When Sulfasuxidine or other intestinal chemotherapeutic agents are used these bacteria become inactive and this important source for preformed amino acids and vitamin K is removed.

The proportion of protein allocated to the liver, blood serum, and kidney is increased as the amount ingested is increased. The liver is enriched quantitatively as well as functionally. This is demonstrated by hyperplasia, hypertrophy, and an increased content of protein per unit weight of tissue. During abstention from food the relative loss is greatest for the liver.

There is not much preformed plasma protein as such and therefore in hemorrhage and shock it must be supplied by intravenous injection until the liver can take hold. However, the instantly available protein together with that less readily available may total one to five times the circulating mass.

Synthesis and Interrelationship of Plasma Proteins.—Plasma proteins are not inert molecules like pectin or acacia. Most tissue proteins are constantly undergoing synthesis and degradation. In the liver more than half of the protein may be broken down and resynthesized in ten days. Labeled amino acids appear within one hour after their ingestion in plasma protein, indicating the rapid build-up of the latter.

Whipple states that there are three kinds of protein: (1) labile reserve readily available for serum protein regeneration; (2) dispensable reserve which is less available; (3) indispensable and fixed of the body cells which is never available. Plasma and tissue cell protein are in 'dynamic equilibrium.'' The dispensable reserves in cells of the liver and all over the body can pass readily into plasma and the reserve without loss of nitrogen. The indispensable proteins may receive contributions from plasma but the reverse is not true because fixed tissue protein cannot be utilized to form proteins of the plasma or liver. Thus a patient may be kept in nitrogen and weight equilibrium by the intravenous administration of plasma and glucose, permitting a build-up of tissue protein as well.

Elman found that the relation between plasma and body protein is 1:30; that is, for every gram of body protein lost or gained, 30 grams of tissue protein are lost or gained during starvation or feeding.

weight (70,000 to 75,000); therefore, it plays *the most important* part in maintaining the colloid *osmotic pressure*. Serum globulin (2.7 grams per 100 c.c.—its osmotic pressure is 1.4 mm. per gram or 3.7 mm.) has a larger molecular weight (150,000 to 190,000) and is present in lower concentration, and fibrinogen (*0.27 grams per 100 c.c.*) has the highest molecular weight (200,000) and the lowest concentration.

Colloid osmotic *pressure is increased due to an artificial increase in colloids, their increased* production, or *their relative* increase due to loss of water. Examples are:

1. Injection of substances with high osmotic index such as blood, plasma, serum, acacia, pectin
2. *Increase in fibrinogen and globulin in tuberculosis, pneumonia*, and other infections, *multiple myeloma*, and also in pregnancy. In the latter the increase is slight or actually reduced if accompanied by hypoalbuminemia
3. Dehydration

It is decreased as a result of diminished ingestion *of protein*, failure of absorption *or synthesis* of *ingested protein, increased loss of protein and relative decrease due to dilution.* Examples are:

1. Starvation
2. Sprue
3. *Hepatic insufficiency*
4. *Massive hemorrhage* (see Chapter 13)
5. Nephrosis
6. Shock (see Chapter 14)
7. Injection of large quantities of fluid intravenously

Since the osmotic pressure within the capillaries is due chiefly to plasma proteins, *it is* well that *we consider these substances with regard to their source, synthesis,* and interrelationship, *functions*, and their ultimate fate.

PLASMA PROTEINS

Source of Plasma Proteins.—Plasma *fibrinogen* and *plasma* albumin are formed exclusively in the liver. Plasma globulin is also formed in *the* liver, augmented *by the* reticulo-*endothelial* system and lymphocytes. The amino acids are selectively absorbed by *the intestinal tract*, not by the lacteals into the lymphatics but by blood capillaries directly *into the portal circulation*, and *synthesized* in the liver into the proteins and plasma protein building material. Some of this is placed *as* reserve stores of plasma proteins in the liver and in other tissues. The fully formed *and fixed* protein *in the* body *cells is not available for the* formation of plasma proteins. There is, however, a dispensable protein *reserve* in the liver and elsewhere which is available for this purpose. The replacement of *plasma* protein *is from two* sources: *exogenous from* ingested foods and endogenous from the reserve stores of plasma protein building material. Not all food contains indispensable amino acids. Milk, for example, *does not contain cystine, an amino acid* which cannot be synthesized in the body. Gelatin is rich in *glycene* but *does not* contain tryptophan and valine which are essential. The indispensable or essential amino acids are *as follows*: *arginine, histidine*, isoleucine, leucine, lysine, methionine, phenylalanine, theonine, tryptophan, *and* valine. Of these, tryptophan, lysine, histidine, and arginine cannot *be* formed from body stores and *therefore must* come *from* the diet which

grams. *This represents the catabolism of 18.75 grams of tissue protein* because each gram of nitrogen represents 6.25 grams of tissue protein; that is, tissue protein contains 16 per cent of nitrogen, or each gram of urinary nitrogen represents the deamination of 6.25 grams of protein. In normal persons 1.3 grams of nitrogen are excreted daily in the feces and 3 grams in the urine. When intake and output are equal, the individual is in *nitrogen equilibrium. A positive* balance indicates that nitro*gen is retained; this is seen in children, in pregnant women, and in adults* recovering from wasting disease or after muscular exercise. A *negative* balance means that output exceeds nitrogen intake.

After surgery the nitrogen loss may be up to 25 grams daily. Amino acid nitrogen of plasma falls during anesthesia. The relationship of tissue protein to water is 1:5. Therefore, a patient losing 25 grams of nitrogen is losing 156.25 grams of protein (25 × 6.25) or 781.25 grams of *tissue protein (156.25 × 5) per day. This is a loss of weight equal to* about 1.63 pounds per day of muscle tissue or its equivalent because wet tissue protein as indicated weighs five times as much as dry protein.

Dextrose spares protein breakdown by supplying adequate calories. Nitrogen balance cannot be obtained by protein alone. This is due to the fact that under such circumstances the excretion of nitrogen always exceeds intake even though the individual ingests protein to his full capacity. *The reason for this is that man cannot consume and digest sufficient* amounts of protein to satisfy energy requirements. He must draw upon stores of carbohydrate and fats. After these are exhausted, protein elements of his tissues are disrupted. The nonnitrogenous portions of the amino acid molecules are burned to make up caloric deficiency, and quantities of nitrogen derived from food and body protein are in consequence excreted. Nonessential tissue fat can supply calories even if dextrose is not given. However, in the postoperative patient the nitrogen loss must be met by exogenous sources.

HYDROSTATIC PRESSURE OF CAPILLARIES

The hydrostatic pressure within the blood capillaries is extremely important in health and disease. Since tissue pressures vary somewhat in different parts of the body, the effective hydrostatic pressure will also vary. In general it may be assumed that where tissue pressure is low, edema is most apt to occur.

The most precipitous fall in pressure occurs in the arterioles. Indeed the arteries with their high presssure are separated from the veins with their low pressure by the arterioles which have been called the "physiological tourniquet." The pressure fall from the aorta to the small arteries is about 20 mm. of mercury; from here to the capillaries, the drop is 60 mm. of mercury. This is due to the frictional resistance which occurs as blood from the large vessels passes through the many small arterioles whose sectional area is only moderately increased, resulting

A low plasma protein leads to great depletion of reserve and thus to liver damage which in turn impedes protein synthesis.

Hypoproteinemia

Liver Impairment ⟶ *Deficient protein Metabolism and reserves*

Impairment ⟵ Metabolism and reserves

Thus we see that plasma proteins represent but a small part of the total body protein and that they do not remain static but are interrelated with the protein of body cells. A normal balance results from the continuous ingestion, absorption, and utilization of protein fractions, and apparently the essential amino acids must be *ingested* at the same time for proper protein synthesis. Parenteral administration of protein hydrolysates are not effective because the selective action of the intestine is lost. Moreover, during the immediate postoperative period practically all of the nitrogen is excreted; and if there is insufficient carbohydrate, the parenteral amino acids lose their nitrogen and the carbohydrate is used for energy.

Functions of plasma proteins.—We have seen that proteins are necessary for the formation of plasma proteins by the liver. This organ is protected against chemical, toxic, and other injury and is able to regenerate liver cells only if it has an adequate supply of protein.

Certain amino acids have a lipotropic activity such as methionine and cystine (with choline) which restrict the intracellular deposition of fat and prevent subsequent fibrosis. This is the rationale for high protein diet with choline (together with vitamin B complex) in atrophic cirrhosis of the liver. See Chapter 22.

Serum albumin is most important in surgery because it is most often depleted due to the size of its molecule which can easily traverse damaged capillaries. It accounts for 85 per cent of the osmotic pressure and this is not entirely compensated by a rise in the other fractions when serum albumin is greatly reduced. Thus serum albumin may be low, serum globulin high, and the total protein normal in amount, but edema and anuria are apt to occur.

Globulin is important in immunity because antibodies and complement are made of globulin and the reticulo-endothelial system is its chief source. The clotting process of blood depends on globulin for fibrinogen, prothrombin, and thromboplastic substance—all are globulins. Fibrinogen can be measured in plasma but not in serum which is expressed from clotted blood or plasma. All of the plasma proteins contribute to the viscosity of the blood, which is said to be a factor in maintaining blood pressure, and they keep the corpuscles more or less adherent.

Fate of Proteins.—The daily urinary excretion of nitrogen in a person on a nitrogen-free diet but of adequate caloric value is around 3

fluids although it comprises only 15 per cent of the total volume of fluid. Its importance lies in the fact that it is the intermediary between the capillaries and the tissue cells. It is therefore the most labile of the three and subject to greater shifts during physiological needs (digestion, sleep, profuse sweating) and morbid states. In the latter it has been called the "buffer" or "cushion" since it may change greatly without alteration of the volume of blood or intracellular fluid.

Much remains unknown about this fluid. In fact, it has been called tissue space, intercellular, extracellular, interstitial fluid to designate it as an individual compartment which in fact does not exist as such but is only a potential "space" permitting its slow circulation together with lymph. Since the capillary wall is freely permeable to water and salts, these occur in about equal concentration on both sides. They are less permeable to proteins and therefore this fluid contains much less protein than the plasma. We have already noted the great variation of this protein content under the discussion of capillary permeability.

Not only is the volume of interstitial fluid subject to variation but to a lesser extent its electrolyte content. The latter is held to within narrow limits in all three compartments, but changes in water and electrolytes occur first in the plasma and interstitial fluid, thus protecting the intracellular fluid which is disturbed only in extreme morbid states.

This is all a part of what Cannon called homeostasis and even here isotonicity is maintained to preserve the integrity of the cell, for the interstitial fluid is the environment in which the cell lives just as was the sodium content of sea water when the first cells began to develop into multicellular organisms, although in the sea the hydrostatic pressure of the animal's cells or capillaries must be greater due to the pressure of the environmental water; and all of the capillary systems can be considered as being at the level of the heart (Krogh). In large aquatic animals, therefore, only a very low osmotic pressure is required to prevent filtration.

The source of interstitial fluid is the capillaries. Fluid moves, as we have seen, because of effective osmotic and hydrostatic pressures. It is returned to the capillaries on the same basis. Protein molecules and excess fluid are returned by the lymphatics which behave as semipermeable membranes dependent on hydrostatic rather than osmotic factors. Fluid in the tissue spaces moves due to muscle contractions and the pulsations of arteries and arterioles. It is lost from the body through the lungs (expired air), the skin (sweating), gastrointestinal tract (secretions and excretions), and the kidneys (urine). The various amounts lost are shown in the accompanying figures. In normal persons the first three (that is, lungs, skin, and gastrointestinal tract) are satisfied first; the water that is left is excreted by the kidneys. In this way the quantity of urine excreted is a reliable indication that other requirements for water have been satisfied provided, of course, that the kidneys are normal. Thus the kidneys act

in only a slight reduction in velocity. Frictional resistance is proportional to the square of the velocity. Therefore, the effect of the greatly increased surface in the arterioles will be to offer a very great resistance to the flow of blood through these vessels.

In the capillary bed pressure falls some and this fall continues to the right side of the heart. In addition, velocity is greatly reduced as blood pours into the "capillary lake." When the arterioles are dilated and more blood flows into the capillaries and veins the pressure in the arteries falls and that in the capillaries and veins rise. If the arterioles are constricted, the reverse occurs. The velocity is high in the arteries but is reduced by several hundred times in the capillaries. Although the capillaries have a very small lumen, their combined sectional area is 800 times greater than the cross area of the aorta. The rate of flow is inversely proportional to the transverse section of the capillary bed. This slowing of the blood flow provides for the interchange of gases and food and the elimination of waste products. If the velocity were not reduced, the frictional resistance would be so great as to cause a further precipitous fall in blood pressure. The slowing of the stream makes frictional resistance little and also tends to raise blood pressure because lateral pressure is inversely proportional to velocity. The rate of flow in the capillaries is subject to little change and therefore they fill up quickly when arterioles dilate, causing an increase in their hydrostatic pressure. Capillaries have no diastolic pressure because this pressure represents the load which the arterial walls are called upon to bear since they are essentially "storage vessels" and the resistance which the ventricular contraction must overcome to open the aortic valves. Since the systolic pressure falls much more than the diastolic peripheral to the arterioles, the two pressures tend to be equal.

The blood current picks up speed in the veins. This is due chiefly to the differences in vascular bed areas and provides for the return of the same quantity of blood to the right atrium as leaves the left ventricle in a given period of time. In the chapters on hemorrhage and shock (Chapters 13 and 14) we shall see that if any part of this closed system of tubes increases or decreases its capacity, the heart may be deprived of this exact balance, temporarily resulting in cardiac inadequacy.

Hydrostatic pressure in the capillaries may be *increased* by (1) vasodilatation of arterioles, (2) obstruction to venous return, (3) increased minute volume output of the heart, and (4) increased blood volume. It is *decreased* by (1) vasoconstriction of arterioles, (2) vasodilatation followed by stasis as seen in inflammations, (3) loss of blood volume with low blood pressure, and (4) decreased minute volume output of the heart.

TISSUE SPACES

We have discussed previously the water compartments of the body. The tissue space fluid is extremely important in the interchange of body

sium inside the cell in accordance with Donnan's theory. If potassium is found in large quantities in the blood or urine, cellular damage has probably occurred. Bicarbonate and phosphate are waste products but they are also important in acid base balance. (See Chapter 12.)

Should sodium be retained in the interstitial fluid, water would also be retained to any amount required so that a normal concentration of sodium would be present. Thus retention of water even to edema levels is a compensatory mechanism designed to protect tissue cells against great increases in electrolyte concentration. Therefore, if water alone is ingested it will be excreted in large measure by the kidneys unless there is an excessive amount of sodium in the tissue spaces; if physiological salt solution is ingested it will be retained or excreted, depending on its need. If salt is lost in excessive amounts or is not ingested, a sodium deficit would occur with loss of water even to a point of dehydration; again so that isotonicity would be maintained. Therefore, interstitial water volume varies with electrolyte concentration and the body can easily increase or decrease the water content through the action of the kidneys, skin, and lungs. Sodium is excreted chiefly through the kidneys.

Glomerular filtrate results from an excess of hydrostatic pressure in the glomerular capillaries over the combined osmotic and intraglomerular pressures (see Chapter 23). This continues in accordance with Starling's hypothesis until the osmotic pressure in the glomerular capillaries due to the concentration of plasma proteins is equal to the *effective hydrostatic pressure. Since the capillaries are usually impermeable* to these proteins, the filtrate contains no protein. The concentration of electrolytes in the filtrate is equal to that of arterial plasma.

In the efferent arteriole the plasma with proteins are much more concentrated (about 20 per cent) when they enter the capillary tuft about the tubules. Here 99 per cent of the water and salts of the glomerular filtrate are reabsorbed, leaving only 1 per cent of the total filtrate to appear as urine.

Perhaps an antidiuretic hormone elaborated by the pituitary gland regulates the reabsorption of water by the kidney tubules. Since the pituitary secretion may be affected by nervous stimuli and by changes in the composition of the blood transmitted to the gland through mediation of the central nervous system, an overproduction or underproduction of this hormone may decrease or increase diuresis in pathological states.

Of the 1100 Gm. of salt filtered off from the blood each day, only *about 5 to 10 Gm. appear in the urine. Ninety per cent of this* reabsorption is due to the increased osmotic pressure in the capillaries surrounding the tubule. The remainder is subject to hormonal control chiefly through the adrenal cortex (desoxycorticosterone). Other steroids such as esterone, progesterone, and tesotosterone play a minor role in this control. Thus an increased body need for salt may be met to a small extent by increased salt reabsorption, a decreased need by decreased reabsorption, resulting in an increase in salt in the urine.

as a compensatory apparatus for excretion of fluid just as the interstitial spaces are a "cushion" for its *storage*.

Should the osmotic pressure of interstitial fluid vary greatly, adjustments would necessarily occur within the cell which must be protected. Therefore, the extracellular fluid retains its isotonicity. *This is accomplished through the action of the kidneys.* Sodium and chloride are the most important electrolytes of plasma and interstitial fluid. Potassium is present in small quantities but is retained by the cells which are impermeable to cations. Sodium, therefore, remains outside and potas-

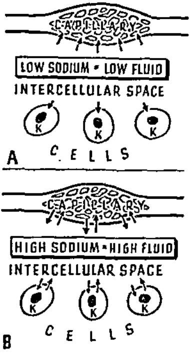

Fig. 96.—Intercellular fluid. The tissue spaces are extremely important in the interchange of body fluids, although they contain only about 15 per cent of the total volume of fluid. The importance of this fluid lies in the fact that it is the intermediary between the capillaries and the tissue cells; therefore it is the most labile of the three compartments; intravascular, intercellular, and intracellular.

The intercellular tissue space fluid has also been called the buffer or the cushion since it may change greatly and quickly without alteration of the fluid content in the capillaries or in the cell. No tissue spaces are actually present which are demonstrable. The space is probably a potential space permitting slow circulation of this fluid together with lymph. It has also been called the extracellular or the interstitial fluid space. *Since the capillary wall is freely permeable to water and salts, these occur in about* equal concentrations on both sides. Capillaries are less permeable to proteins and, therefore, there is less protein in the interstitial spaces than in the blood stream. The protein which is lost is picked up by the lymphatics and carried back to the blood stream.

The cell contains potassium and the interstitial spaces chiefly sodium. Potassium is retained by the cells which are impermeable to cations. Sodium, therefore, remains outside of the cell and potassium inside the cell in accordance with Donnan's theory. The filtration of fluid depends upon the effective osmotic or hydrostatic pressure as described in the text. Isotonicity must be maintained so that the cells may be preserved.

A. This diagram illustrates what happens when there is an absence or almost complete absence of sodium in the intercellular space. Should much fluid be present, it would become hypotonic, and, of course, the tissue cell would become plethoric and probably be damaged. Therefore, when sodium is low in the intercellular tissue space, fluid is lost so that isotonicity is maintained.

B. When sodium is high in the intercellular tissue space, much fluid is retained. Here again the purpose is to preserve the cell, and this is done through isotonicity. When sodium is present in excessive amounts in the *intercellular tissue spaces, water is retained* to preserve isotonicity and then water and sodium are lost through the kidneys. Should the kidneys be unable to excrete the excess sodium, fluid will be retained to preserve isotonicity, and edema *will occur.*

is able to diffuse freely into the majority of cells. However, in most instances the physical forces above described are insufficient to account for the exchange of substances. Krogh reports the problems raised by Heidenhain concerning the transport of calcium from the blood to the milk in the cow. "The cow produces milk at the rate of 25 liters a day, with a calcium content of 42.5 grams or 1.7 grams per liter. This *quantity of calcium is derived from the blood, in which the calcium content does not* exceed 0.18 gram per liter. The calcium ions cannot possibly move spontaneously from the blood to the alveoli of the mammary gland. Their transport must involve the expenditure of energy, must involve work performed in living cells by means of some special 'machinery,' so far utterly unknown, adapted for the purpose; must involve, in short, *secretion* of calcium."

Thus cells, in addition to their behavior as semipermeable membranes, enter actively into the production of products necessary to life. However, they are literally a fluid within a fluid separated only by the cell membrane. Therefore, they are susceptible to changes in their environment. Moreover, if the cell wall is damaged, their chief cation potassium is lost into the intercellular fluid, appearing finally in the urine in larger quantity than normal. This finding then may be an indication of cell damage, and it is understandable why changes in sodium concentration occur rapidly, whereas changes in potassium occur slowly. The term "available water" is only relative. When the blood needs fluid it is taken from the intercellular compartments. With the loss of fluid there is loss of electrolytes. These must be replaced or severe hyponatremia results, disturbing osmotic relations between cells and intercellular fluid. Intracellular water will be pulled out by the increase in ionic concentration in the intercellular fluid, thereby depriving the cell of its water. Exchange of gases will be disturbed due to stagnant anoxemia with resulting tissue anoxia. This in turn injures the cell wall, causing it to lose its cations (chiefly potassium), thereby further disturbing its metabolism. The loss of potassium from the cell ultimately results in hypokalemia due to increased excretion of potassium in the urine. The sodium content of the cell is then increased and serum bicarbonate is high to maintain biological equilibrium. *Chloride is excreted and bicarbonate retained. Potassium chloride* is necessary to increase intracellular potassium and lower intracellular sodium and to cause an increase in serum chloride and a decrease in serum bicarbonate.

Either inadequate intake or excessive loss of salt and water through the kidneys or gastrointestinal tract may produce this picture. Obviously the changes noted here in the cells are secondary to those in the blood. Plasma volume is greatly decreased; serum protein hematocrit and red blood counts are increased. Concentrations of sodium and chloride are decreased, while potassium is increased. If the dehydration is complicated by acidosis as in untreated diabetes mellitus, serum bicarbonate is decreased.

If vomiting occurs due to pyloric obstruction with loss of chloride, the blood becomes more alkaline and the concentration of blood bi-

In Addison's disease the control is lost but the mechanism remains intact. Here salt is lost and with it much extracellular fluid (see Chapter 22). If the glomerulus is damaged, as in acute glomerulonephritis, less salt will be filtered but the tubules take back their usual amount. This results in salt retention and edema. If both glomerulus and tubule are damaged, the effects will depend on which predominates. Tubule damage means salt loss with dehydration.

Tissue pressure is almost everywhere equal to atmospheric pressure except in the lower part of the abdominal cavity, where there is a positive pressure due to the weight of the intestines, and in the pleural cavity, where there is a negative pressure (see Chapter 14). The pressure in the pleural cavity is about 6 mm. of mercury (80 mm. of water) lower than atmospheric. The cause of this (Krogh) is that the pleural cavity is sufficiently resistant mechanically to allow definite pressure differences to occur. The colloid osmotic pressure of the blood is normally about 360 to 400 mm. of water, while the hydrostatic pressure in the capillaries of the pleural cavity and surface of the lungs is much less. "Therefore water will be drawn (with crystalloids) from the cavity into the blood and thereby expand the lungs of the newborn and keep them expanded thenceforward" (Krogh).

The hydrostatic pressure in the *tissue spaces* may be *increased* by (1) increased filtration from the capillaries from any cause, (2) obstruction to the lymph return, (3) increased osmotic pressure due to damaged capillaries, as in traumatic shock or inflammations, and (4) prerenal deviation of water and salt, due to the lag between ingestion and excretion of salt and to storage of water and salt in the skin and subcutaneous tissues. This may be due to increased activity of pituitary antidiuretic hormone from nervous or other causes.

The osmotic pressure in the tissue spaces is increased due to loss of protein through permeable capillaries or obstructed lymphatics.

Lymph.—The lymph capillaries help drain the tissue spaces (see Chapter 17).

An *increase in lymph flow* may be due to (1) increased intercellular pressure in the tissue spaces, (2) active motion, (3) passive motion and massage.

A *decrease in lymph flow* may be due to (1) decreased filtration of fluid from the capillaries, (2) obstruction of the lymphatics from lymphangitis, new growth, fibrosis, infection with *filaria sanguinis-hominis*, or familial lymphedema (Milroy's disease).

INTRACELLULAR FLUID

Most of the body's fluid is in its cells. We have already considered the elaborate precaution which nature takes to protect this fluid and the tenacity with which the cells hold on to it. Ionic concentrations on either side of the cell membrane must be the same for osmotic reasons.

The Donnan theory of membrane equilibrium predicts the distribution of ions which will take place on either side of a membrane which is impermeable to one of the ions. It has been used to explain the exchange of anions (chloride and bicarbonate) between the plasma and the interior of the red blood cell conditioned by the impermeability of the red cell membrane to sodium, potassium, and other cations.

In general, gases enter or leave cells by simple physical diffusion (although special mechanisms exist for the transport of oxygen and carbon dioxide in the blood). Urea

Salt.—Water is taken into the body as a matter of habit in America. Other liquids are substituted in countries where water supply is not as available or potable. Such liquids are chiefly wines diluted with water. The body is warned of the need for water by *the sensation of thirst. This* phenomenon according to Talbott, Dill and others is little understood. It depends on diminished water content and increased osmotic pressure of body cells rather than a dry mouth, although the latter may have a common origin with the former. Contractions of the smooth muscle of the esophagus may play a role.

A small increase in osmotic pressure produced by sodium chloride creates an intense thirst. Yet the ability to distinguish between a desire for salt and a desire for water is poorly developed in man although highly developed in animals. The normal individual uses about 5 Gm. of sodium chloride per day. The volume of sweat in eight hours of hard work in hot weather is said to be 10 to 15 liters and each liter contains 3 to 4 Gm. of salt. Therefore, water alone cannot satisfy thirst when both water and salt are lost. This is well known to those in hot climates or those who supervise the health of employees working in extreme heat in factories, boiler rooms, etc. Water alone without salt, as we have seen, leads to shrinkage of interstitial fluid volume, leading to dehydration in spite of water intake. Tropical languor characterized by weakness, fatigue, and anorexia in sedentary persons and muscle cramps in those engaged in hard work are evidences of salt deficiency, not water intoxication. Sometimes a shocklike syndrome occurs with loss of weight, weakness, apathy, anorexia, hypotension, orthostatic fainting, but there is *very little thirst* and an ample output of urine. Such individuals need 15 Gm. of salt daily with water. The excess NaCl will be excreted.

True dehydration consists of a great diminution of water without an associated loss of salt. This is a shortage of water in relation to solutes. Water is retained in the interstitial spaces for osmotic reasons (hypernatremia) and yields to the blood stream because of the osmotic pressure of plasma proteins. There is no hemoconcentration for some time; there is *severe thirst* and oliguria with azotemia. The kidneys do not excrete this excessive amount of salt. Such individuals need water. In clinical practice combinations are encountered. For example, an obstruction of the esophagus would lead to an absence of water, alone without loss of salt, whereas severe diarrhea, vomiting, intestinal fistulae, and Addison's disease cause a deficiency in electrolytes and water.

Salt Block.—The excessive parenteral administration of salt solution may bring about a condition known as salt block, which is characterized by *edema, anuria,* and *high fever,* followed in some cases by delirium and even death. Torbert and Cheney found a reduction in colloidal osmotic pressure of the blood serum after the ingestion of large amounts of sodium chloride (20 to 60 Gm. daily). The blood chlorides rise to high levels. Salt is more important than water because if salt

carbonate is increased. Later if the kidneys fail to excrete nitrogen azotemia results. This is late because the kidneys can make a hypertonic urine and may continue to excrete nitrogen products in a small amount of urine. Under these conditions, as we have seen, the tubules will reabsorb practically all of the sodium chloride. Finally with a decreasing plasma volume, flow through the glomerular capillaries is greatly diminished; blood viscosity is increased as proteins are concentrated; hydrostatic pressure is inadequate to form glomerular filtrate with resulting anuria.

Such a picture is not common in clinical practice where proper measures are introduced before this stage, which may take several days, has had a chance to occur. Since potassium is the chief cation within the cell, its depletion causes great changes inside and outside of the cell membrane. Hypokalemia may be caused by lack of intake in food, large amounts of glucose and saline infusion, vomiting, and the ingestion of ammonium chloride or the administration of testosterone. When intracellular potassium is reduced and intracellular sodium increased, biological equilibrium is achieved by a high serum bicarbonate and an increase in urinary chloride excretion. Thus alkalosis with hypochloremia and hypokalemia exist together. Gamble and co-workers showed that in order to keep the total milliosmols around 310 milliosmols per liter, potassium leaves when sodium is added. Therefore potassium and not sodium must be given.

The measurements of the osmotic features of extracellular fluid components are best stated in terms of ionic concentration. According to Gamble, the valency is disregarded. He suggests the term milliosmols per liter (milligrams per liter divided by atomic weight). Milliosmolar and milliequivalent values for the univalent ions are the same. The chemical equivalents of divalent ions are twice their milliosmolar value. Gamble suggests that the term milliosmolar be used instead of millimolar to make clear the osmotic effect of individual ions. In other words, the milliosmolar value of a solution of sodium chloride is twice its millimolar value. The normal value for ionic concentration of extracellular fluid as a whole is 310 milliosmoles per liter.

FACTORS AFFECTING THE NORMAL WATER BALANCE

Water is the most abundant constituent of the tissues and is taken up and released more rapidly than any other substance. When only 10 per cent of the body water is lost, serious subhydration occurs. Water is taken into the body by fluids drunk and by food eaten. Solid food is a source of water not only because most foods are about 70 per cent water, but also because in the process of oxidation of food in the body, water is formed. Even if no food or fluid is ingested, about 500 c.c. of water per day become available (during the first days of a fast) due to body tissue metabolism.

Adolph states that the daily water turnover is about four gallons. Since the stomach absorbs nothing (except alcohol) it must be looked upon as a storage tank for food and water, whereas the colon is an absorption system for the conservation of water. Phylogenetically these organs were designed to give man freedom in his environment. Since he can do without food due to fat and other deposits for longer periods than he can be without water, a method is provided for conserving the latter.

Although the vaporization process takes precedence, the kidneys will do their work with whatever fluid is available. If ample fluid is taken, the specific gravity of the urine will be low (assuming kidney function to be normal); if not, the specific gravity will be high. Therefore, a small quantity of highly concentrated urine (high specific gravity) means probably that insufficient water is being taken and that the body is maintaining a normal water balance. (Oliguria due to kidney damage or to ureteral obstruction should be ruled out by giving adequate amounts of water.)

The movement of water is intimately associated also with the distribution of electrolytes; the concentration of each ion is maintained through the retention or elimination of water. In the body fluids the chief basic ions are Na^+ and K^+ (sodium in extracellular fluids and potassium in intracellular), and the chief acid radicals are HCO_3^- and Cl^-. The sum of the basic ions must balance the sum of the acid ions. Loss of Cl^- can be made good by the retention of HCO_3^- and a rise in plasma bicarbonate. Excreted base can be *replaced only by basic substances supplied in the food or given parenterally.* The total concentration of electrolytes is therefore dependent upon the amount of base stored. Therefore, the body retains base. Acids are the products of metabolism and are excreted in large quantities. The kidneys compensate by altering the balance between sodium acid phosphate (NaH_2PO_4) and basic acid phosphate (Na_2HPO_4). On an ordinary mixed diet containing meat the urine is acid; that is, there is a relative excess of Na_2HPO_4. On a vegetable diet the urine is alkaline with a relative excess of Na_2HPO_4.

Whenever there is an excess of alkali in the body there is an increase in plasma bicarbonate, and base Na^+ or K^+) will be lost, for the urine will contain a larger proportion of Na_2HPO_4. Thus in dehydration due to pyloric obstruction, as Gamble has shown, glucose solution, water, or water with chlorine ions will not restore water balance; sodium chloride is needed. If there is an excess of acid, there will be a decrease in plasma bicarbonate, and radicals (HCO_3^-; Cl^-) will be excreted and the urine will contain an excess of acid phosphate (NaH_2PO_4). This is illustrated when base depletion is a primary cause of dehydration (biliary, pancreatic, or intestinal fistulae) or when as a result of dehydration the kidneys are impaired and do not reabsorb a sufficient amount of sodium. However, with acid or base there is increased diuresis

is retained (hypernatremia) water must be. *Water can be eliminated easily (skin, lungs, kidneys, intestinal tract).* Salt with sodium is *retained* when *given* intravenously after operation. Perhaps as in burns and other trauma, it is due to an increased tissue demand for salt, especially in the traumatized areas, and the inability of the kidneys to excrete it. With this salt much water is also retained in the interstitial spaces and is not available for vaporization, perspiration, and urine. If the normal person needs 5 Gm. of *sodium chloride per day and if 3,000* c.c. of physiological *salt solution is given intravenously, then 27 Gm.* of salt *are introduced.* This may lead to retention of salt which calls upon the intracellular fluid to maintain isotonicity in the tissues. Under such conditions edema is a protective mechanism. But the kidneys do not excrete salt in sufficient quantities to maintain isotonicity. Such salt retention leads to oliguria with more salt retention, more water bound, coming from the intracellular fluid with dehydration of cells and impairment of their *function, especially the brain, which is shown clinically by delirium and disorientation, and the kidney, shown by anuria. Coller* and associates recommend the infusion of hypotonic solutions *(0.45 NaCl* or 0.38 per cent NaCl plus 0.11 per cent $NaHCO_3$) postoperatively for forty-eight hours during the salt intolerance period. The administration of 5 per cent glucose in distilled water is specific, reducing the edema and restoring normal urinary function. It is probably the discontinuance of the salt and the adequate supply of water, rather than the glucose, that helps.

Movement of Water.—Water is lost by vaporization from the skin *to regulate the body temperature. Twenty-five per cent of the body heat is dissipated in this way (the other 75 per cent is lost by radiation,* conduction, and convection). *According to Newburgh, this 25 per cent* equals a loss of about 1,000 to 15,000 c.c. of water daily, *varying with* the need of sweating. Maddock and Coller assert that this water takes preference over water used by the kidneys. Kidney function is dependent on water intake. The kidneys excrete about 35 Gm. of waste material daily. If they function normally, they may accomplish this by the use of about 500 c.c. of water. Since kidney function varies with various activities in pathological states, this amount is usually inadequate. The average requirement is about 1,500 c.c. of water for excretion *daily. Of water that is ingested,* 70 to 80 per cent is excreted within *two hours, and about 25 to 30 per cent in half an hour.*

Lesser *amounts of water (about 300 c.c. daily) are lost* by the lungs, which aid in vaporization. *(In the dog there are no sweat glands and* vaporization is carried out almost *entirely through the lungs). About* 150 c.c. of fluid is lost in the feces normally. The reason *the amount is* small is that most of the 7 to 10 liters poured into the *gastrointestinal and* pancreatic juices and the bile is absorbed in the colon.

About 500 c.c. of bile are secreted daily 1,000 to 2,000 c.c. of gastric juice, 500 to 1,500 c.c. of saliva, 700 to 1,000 c.c. of pancreatic juice, 700 to 3,000 c.c. of intestinal secretion (succus entericus).

Adolph states that the daily water turnover is about four gallons. Since the stomach absorbs nothing (except alcohol) it must be looked upon as a storage tank for food and water, whereas the colon is an absorption system for the conservation of water. Phylogenetically these organs were designed to give man freedom in his environment. Since he can do without food due to fat and other deposits for longer periods than he can be without water, a method is provided for conserving the latter.

Although the vaporization process takes precedence, the kidneys will do their work with whatever fluid is available. If ample fluid is taken, the specific gravity of the urine will be low (assuming kidney function to be normal); if not, the specific gravity will be high. Therefore, a small quantity of highly concentrated urine (high specific gravity) means probably that insufficient water is being taken and that the body is maintaining a normal water balance. (Oliguria due to kidney damage or to ureteral obstruction should be ruled out by giving adequate amounts of water.)

The movement of water is intimately associated also with the distribution of electrolytes; the concentration of each ion is maintained through the retention or elimination of water. In the body fluids the chief basic ions are Na^+ and K^+ (sodium in extracellular fluids and potassium in intracellular), and the chief acid radicals are HCO_3^- and Cl^-. The sum of the basic ions must balance the sum of the acid ions. Loss of Cl^- can be made good by the retention of HCO_3^- and a rise in plasma bicarbonate. Excreted base can be *replaced only by basic substances supplied in the food or given parenterally*. The total concentration of electrolytes is therefore dependent upon the amount of base stored. Therefore, the body retains base. Acids are the products of metabolism and are excreted in large quantities. The kidneys compensate by altering the balance between sodium acid phosphate (NaH_2PO_4) and basic acid phosphate (Na_2HPO_4). On an ordinary mixed diet containing meat the urine is acid; that is, there is a relative excess of Na_2HPO_4. On a vegetable diet the urine is alkaline with a relative excess of Na_2HPO_4.

Whenever there is an excess of alkali in the body there is an increase in plasma bicarbonate, and base Na^+ or K^+) will be lost, for the urine will contain a larger proportion of Na_2HPO_4. Thus in dehydration due to pyloric obstruction, as Gamble has shown, glucose solution, water, or water with chlorine ions will not restore water balance; sodium chloride is needed. If there is an excess of acid, there will be a decrease in plasma bicarbonate, and radicals (HCO_3^-; Cl^-) will be excreted and the urine will contain an excess of acid phosphate (NaH_2PO_4) This is illustrated when base depletion is a primary cause of dehydration (biliary, pancreatic, or intestinal fistulae) or when as a result of dehydration the kidneys are impaired and do not reabsorb a sufficient amount of sodium. However, with acid or base there is increased diuresis

because water moves with electrolytes and electrolytes move with water, leading to subhydration unless restored. Sometimes acid-producing salts are used as diuretics.

Clinical Application of Starling's Theory.—Let us now consider the application of Starling's theory in some physiological and pathological states. It is apparent that three factors must be borne in mind; namely, the effective hydrostatic pressure, the effective osmotic pressure, and the permeability of the capillaries. Since in many conditions more than one factor may be at work, it is often difficult to categorize such causes. Naturally one aberration leads to others. Therefore, we shall consider the primary factors in the discussion pointing out accessory or secondary effects as well.

Hydrostatic Pressure Changes.—Venous stasis produces edema not only through an increase in hydrostatic pressure, but also through an increase in capillary permeability brought about by stagnant anoxia. This is exemplified in the general edema of cardiac decompensation (although there may be kidney damage also, decreasing its functional capacity for sodium excretion), in the accumulation of fluid in the abdomen (ascites) due to portal hypertension as in cirrhosis of the liver (here leaky capillaries due to portal anoxemia play a role), in the face and neck upon obstruction of the superior vena cava from aneurysm of the aorta and mediastinal tumors, and in the legs from thrombophlebitis.

In cardiac decompensation with ascites the effective hydrostatic pressure in the abdominal veins is somewhat decreased due to the fluid in the abdominal cavity. In this way the veins are supported so that they do not continue to dilate. When ascitic fluid is suddenly removed, much dilation occurs with an increased pooling of blood and sometimes resulting shock.

In peripheral vascular disease obstruction to the veins or the lymphatics causes edema. The venules have an increased hydrostatic pressure.

This may be produced experimentally by the application of a rubber cuff to the extremity. Mende showed that when the pressure was raised to 100 cm. of water an increase in volume of about 40 c.c. took place. During the next fifteen minutes a further increase of 60 c.c. took place. This continued for a further period of twenty minutes when decompression took place after a total increase in volume of 120 c.c. On decompression the volume went down about 70 c.c. in two minutes and thereafter took thirty-five minutes to regain the original volume.

In hemorrhage there is a loss of blood volume. The hydrostatic pressure is reduced and the osmotic pressure is unchanged, so that fluid will be drawn into the blood stream. The concentration of the blood cells and of the protein will be lowered due to the space-filling effect of the migrated intercellular fluid, although more red blood cells would give a more permanent addition to the circulating blood volume.

In old people who are kept in the recumbent position for long periods, the venous flow is decreased because the venous return depends partially on muscular action. (Long inhalation anesthetics and spinal anesthetics have the same effect.) In addition, the hydrostatic pressure in the capillaries is decreased due to a pooling of the blood in the venules, which decreases the volume of the circulating blood. The arterioles contract to offset this and a shocklike state ensues. This may give rise to edema (due to increased permeability of capillaries from stagnant anoxia) or to thrombosis. (Pain in the extremities at night in patients with arteriosclerosis is probably due to an insufficient blood supply caused by a lowered blood pressure.)

Osmotic Pressure Changes.—In loss of fluid (anhydremia) by diarrhea, vomiting, excessive sweating, or excessive diuresis the blood plasma becomes concentrated and water is drawn into the blood stream. There is an increase in the concentration of the plasma protein as well as an elevation of the red blood cell count and as a result the blood is thick (hemoconcentration).

Saline cathartics cause water to enter the bowel because of the osmotic pull of the concentrated salt solution. In this way they draw water from the tissues. Postprandial thirst (a milder form of dehydration) is explained in the same manner.

"If the distribution of the absorbed water and crystalloids between the blood and the chyle is to be at all explicable as the result of simple osmotic processes, the concentration of each substance in the chyle must never be lower than in the blood, while the quantity of chyle flowing from the intestine per unit time must be at least somewhat higher than the corresponding quantity of lymph flowing from the empty gut." (Krogh.) If this is true, water will be drawn out of the capillaries surrounding the intestines, and diffusible substances will enter the blood stream. After complete equilibrium, the increased colloid osmotic pressure in the capillaries reabsorbs water from the intestine.

Shock is due to a loss of blood plasma into the injured area through traumatized and abnormally permeable capillaries. The loss of blood volume lowers the hydrostatic pressure; the loss of plasma protein lowers the osmotic pressure; the capillaries become packed with cells, due to the stagnation of the viscid blood. Capillary pressure rises and transudation of fluid is increased. If any fluid is absorbed from the tissues it is promptly lost from the capillaries in the injured area and thus a vicious circle is established. If large quantities of fluid are given intravenously, the hydrostatic pressure will be increased and more plasma will be lost with the fluid into the injured area, decreasing further the osmotic pressure; as a result water will leave the capillaries throughout the body, causing so-called "water intoxication."

In infections the capillaries become more permeable and plasma proteins exude together with inflammatory cells, at the site of inflammation.

Lewis believes that *inflammation* (as described in Chapters 4 and 5) is due to the liberation of *H-substance*, a *product of tissue cells that are exposed to injury of any kind.* The whole reaction is a defensive mechanism *which counteracts the injury without calling upon the central organization of the body.*

The osmotic pressure of the tissue fluid in this area rises until it equals that of the blood, so that absorption will not take place (Chapters 4 and 5).

Capillary Permeability.—Capillary permeability may be affected in such conditions as pernicious anemia, leucemia, angioneurotic edema, and Addison's disease but usually it is a combination of the factors mentioned which cause edema. This is seen in the cachectic states of carcinoma and late tuberculosis.

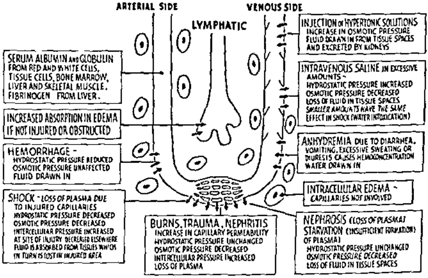

Fig. 97.—Diagram illustrating examples of interchange of fluid in abnormal conditions. A capillary loop and collaterals are represented; also a lymphatic capillary. Where plasma has been lost, it is necessary to supply this first before giving intravenous saline, so that the latter may be retained within the capillaries. Therefore a red blood count and hemoglobin determination should be done to determine the degree of hemoconcentration before intravenous medication is begun.

Edema.—Edema may result from an increase in hydrostatic pressure, a decrease in osmotic pressure, increased capillary permeability, or lymph blockage. We have considered all of these factors previously in relation to the three water compartments. Thus we may say that *edema* is an extrarenal phenomenon although the kidneys play an important role. However, even in acute glomerulonephritis the edema may be due to a general capillary disease. When both kidneys are removed in the experimental animal, edema does not develop. Water is removed by extrarenal means as it is normally. This amounts to 40 per cent of water excretion. Oliguria is the result, not the cause, of the edema. *Renal* edema is divided into two types: nephritic and nephrotic. *Nephritic* edema occurs in acute glomerulonephritis. It is due at least in part to an increased permeability of the capillaries because the edema fluid contains over 1 per cent protein. The capillaries of the *subcutaneous tis-*

sues are injured by the same toxins which act on the capillaries of the glomeruli. It is therefore an inflammatory edema. It may also be due to an elevation of hydrostatic pressure in the capillaries when there is an associated congestive failure. Nephrotic edema occurs in chronic nephrosis, the nephrotic stage of glomerulonephritis, and in amyloid kidney. The protein content of this edema is 0.1 per cent. This is due to loss of albumin principally, as shown by the reversed albumin globulin ratio. Chronic renal edema improves as the kidney becomes more impaired. This is due to the fact that less albumin is lost, causing blood proteins to rise, increasing osmotic pressure. A secondary cause of renal edema is the retention of sodium as previously discussed.

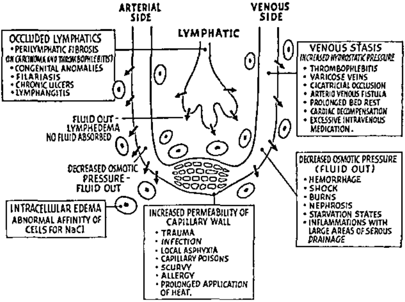

Fig. 98.—Diagram illustrating the mechanism of edema in the extremities. The arterial and venous sides of the blood capillaries are shown, also the lymphatic capillary. It is well to remember that more than one factor may be at fault. Not represented is the element of spasm, which occurs in both veins and arteries as a result of thrombophlebitis. This increases venous pressure, decreases arterial blood, and thereby further promotes anoxia with more permeability of the capillaries. Arterial pulsation normally aids in the movement of lymph, absence of pulsation retards this movement.

Dehydration.—When the output of water exceeds the intake, dehydration results. This may occur from insufficient intake of fluid and food, excessive loss of water, reduction in electrolytes, or the injection of hypertonic solutions. Maddock and Coller have shown that the greatest loss of fluids in the surgical patient occurs postoperatively, due to vaporization through excessive sweating. In addition, fluid is lost by vomiting and in the urine. Excessive fluid may be lost also in conditions with high fever (vaporization). Sweating occasions the loss of much salt as well and therefore may create a hypochloremia with alkalosis. Other causes which are not physiological (absolute losses) are blood loss, vomitus, drainage from intestinal and biliary fistulae, diarrhea, and massive exudation from inflamed surfaces (such as infections and burns).

Lewis believes that inflammation (as described in Chapters 4 and 5) is due to the liberation of *H-substance*, a product of tissue cells that are exposed to injury of any kind. The whole reaction is a defensive mechanism which *counteracts the injury without calling upon the central organization of the body.*

The *osmotic pressure of the tissue fluid in this area rises until it equals that of the blood, so that absorption will not take place* (Chapters 4 and 5).

Capillary Permeability.—Capillary permeability may be affected in such conditions as pernicious anemia, leucemia, angioneurotic edema, and Addison's disease but usually it is a combination of the factors mentioned which cause edema. This is seen in the cachectic states of carcinoma and late tuberculosis.

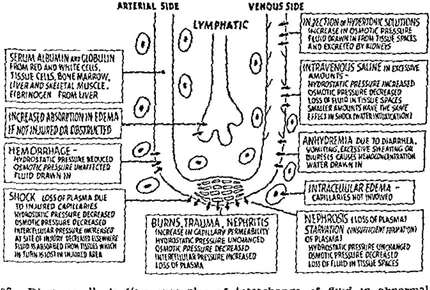

Fig. 37.—Diagram illustrating examples of interchange of fluid in abnormal conditions. A capillary loop and collaterals are represented; also a lymphatic capillary. Where plasma has been lost, it is necessary to supply this first before giving intravenous saline, so that the latter may be retained within the capillaries. Therefore a red blood count and hemoglobin determination should be done to determine the degree of hemoconcentration before intravenous medication is begun.

Edema.—Edema may result from an increase in hydrostatic pressure, a decrease in osmotic pressure, increased capillary permeability, or lymph blockage. We have considered all of these factors previously in relation to the three water compartments. Thus we may say that edema is an extrarenal phenomenon although the kidneys play an important role. However, even in acute glomerulonephritis the edema may be due to a general capillary disease. When both kidneys are removed in the experimental animal, edema does not develop. Water is removed by extrarenal means as it is normally. This amounts to 40 per cent of water excretion. Oliguria is the result, not the cause, of the edema. Renal edema is divided into two types: nephritic and nephrotic. Nephritic edema occurs in acute glomerulonephritis. It is due at least in part to an increased permeability of the capillaries because the edema fluid contains over 1 per cent protein. The capillaries of the subcutaneous tis-

sues are injured by the same toxins which act on the capillaries of the glomeruli. *It is therefore an inflammatory edema. It may also be due* to an elevation of hydrostatic pressure in the capillaries when there is an associated congestive failure. Nephrotic edema occurs in chronic nephrosis, the nephrotic stage of glomerulonephritis, and in amyloid kidney. The protein content of this edema is 0.1 per cent. This is due to loss of albumin principally, as shown by the reversed albumin globulin ratio. Chronic renal edema improves as the kidney becomes more impaired. This is due to the fact that less albumin is lost, causing blood proteins to rise, increasing osmotic pressure. A secondary cause of renal edema is the retention of sodium as previously discussed.

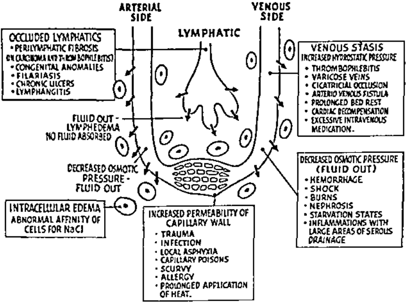

Fig. 98.—Diagram illustrating the mechanism of edema in the extremities. The arterial and venous sides of the blood capillaries are shown, also the lymphatic capillary. It is well to remember that more than one factor may be at fault. Not represented is the element of spasm, which occurs in both veins and arteries as a result of thrombophlebitis. This increases venous pressure, decreases arterial blood, and thereby further promotes anoxia with more permeability of the capillaries. Arterial pulsation normally aids in the movement of lymph, absence of pulsation retards this movement.

Dehydration.—When the output of water exceeds the intake, dehydration results. This may occur from insufficient intake of fluid and food, excessive loss of water, reduction in electrolytes, or the injection of hypertonic solutions. Maddock and Coller have shown that the greatest loss of fluids in the surgical patient occurs postoperatively, due to vaporization through excessive sweating. In addition, fluid is lost by vomiting and in the urine. Excessive fluid may be lost also in conditions with high fever *(vaporization). Sweating occasions the loss of much* salt as well and therefore may create a hypochloremia with alkalosis. Other causes which are not physiological (absolute losses) are blood loss, vomitus, drainage from intestinal and biliary fistulae, diarrhea, and massive exudation from inflamed surfaces (such as infections and burns).

Another example of dehydration is seen in diabetic coma. The important factor here is an excess of beta hydroxybutyric and acetoacetic acid (products of disturbed metabolism of fats known as ketone bodies; formed in the liver). These acids combine with the base of bicarbonate to form salts that are excreted in the urine. The bicarbonate of the blood is thus reduced. At the same time the output of urine is increased because of the increased amount of material to be eliminated. (Ammonia excretion is also increased.) In addition there is dyspnea which actually amounts to air hunger, due to acidotic stimulation of the respiratory center. Thus, great amounts of fluid are lost by the kidneys, the lungs, and the skin (through diuresis, labored breathing, and sweating) and the result is dehydration.

In intestinal obstruction the loss of gastric hydrochloric acid by excessive vomiting lowers the blood chloride (hypochloremia); carbon dioxide is retained to compensate for the lost chloride and there results an increase in plasma bicarbonate. The excess of base constitutes an alkalosis. If the blood becomes definitely alkaline (pH, 7.6), tetany may occur. (See Chapters 12 and 20.) Nature attempts to counteract an alkalosis by an increased excretion of fixed base in the urine (which becomes alkaline and shows a decrease in ammonia content); breathing is depressed (in order to retain carbon dioxide) and the alveolar CO_2 ten-

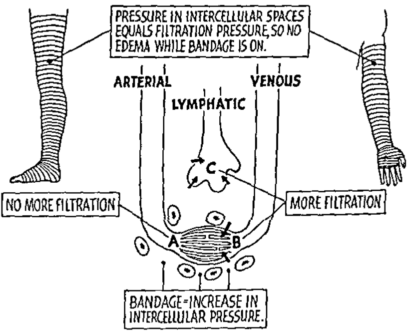

FIG. 99.—Diagram illustrating the effect of bandage treatment on edema in the extremities. A compression elastic bandage is tightly applied, as shown, *for ten minutes*; it is then removed and the extremity is massaged. This is repeated at frequent intervals. The bandage raises intercellular pressure and also intracapillary hydrostatic pressure until the two are equal. This precludes filtration of fluid by hydrostatic forces, but the osmotic pull of the blood absorbs water, and, if the lymphatics are unobstructed, *proteins are absorbed as well. Since lymph is propelled by* external compression (due normally to muscular contraction, motion, and arterial pulsation), the intermittent method of pressure *is superior to continuous pressure in lymphatic stasis.* Because of the increased intravenous pressure due to bandage (which must be less than systolic pressure) new collaterals will form and thereby improve *the venous return.* Edema due to thrombophlebitis may be helped by the injection of procaine into the sympathetics (paralyzing the vasoconstrictors) or more easily by the use of *local* heat. *This relaxes the spasm* of the veins involved and also the arteries, decreasing intravenous pressure and increasing arterial inflow, thereby reducing the stagnant anoxia and *capillary* leakage. *Elevation of the part* empties the veins, decreases hydrostatic pressure, and aids in the treatment of postphlebitic, but not lymphatic, edema.

sion is increased. More water is needed to accomplish the excretion of the excess base, and since there is less sodium, less water remains in the tissues for osmotic reasons and dehydration results.

In severe diarrheas pancreatic juice with much base is lost; consequently plasma bicarbonate is reduced (acidosis), and acid radicals are excreted in the urine. Great amounts of water are thus lost through the diarrhea and the water used by the kidneys. The loss of base in such conditions is a primary cause of dehydration. Later there is impaired renal function and more loss of base.

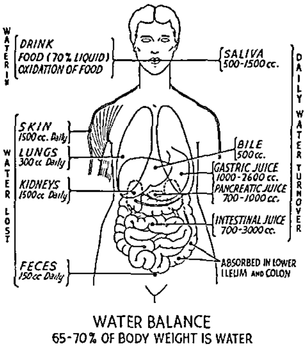

Fig. 100.—Diagram illustrating the water balance of the body. Water is obtained from liquids, food, and the oxidation of food. It is lost through the skin, lungs, kidneys, and feces. About four gallons of water are secreted by various glands and absorbed in the lower ileum and colon.

In most conditions in which there is dehydration there is also a loss of protein which occurs due to increased capillary permeability (infections, stagnant anoxemia, anoxic anoxemia when great distention of the bowel occurs), trauma to tissue at operation, as well as diminished supply due to starvation or liver damage. Therefore, it is well to consider *abnormalities in protein in relation to the amount of water and electrolytes.*

Hyperproteinemia and Its Relation to Dehydration.—In dehydration there is an increase in serum proteins, chiefly globulin. Should it continue, stagnant anoxemia develops, capillaries lose *protein*, and dehydration shock follows. The rapid concentration of blood, whether it occurs from loss of whole plasma (burns, trauma) or the protein fraction (plasmapheresis), or the aqueous fraction, leads to deficient oxy-

genation. This results in dilatation and an increase in the number of functioning capillaries so that an increased diffusion of oxygen can occur. The increased dilation and permeability is due to the local effect of poorly oxygenated blood. Pulmonary capillaries are also congested leading to pulmonary edema with more anoxia.

Hyperproteinemia is almost always due to an increase in serum globulin except in hepatic disease, acute glomerulonephritis, and where there is a simultaneous occurrence of two conditions—one causing hyperglobulinemia, the other hypoalbuminemia. Hyperglobulinemia is said to exist if the serum globulin is above 3 Gm. per 100 c.c. This is usually due to chronic infections, such as syphilis, lymphopathia venereum, and tuberculosis. Serum proteins above 9 Gm. are rarely found except in multiple

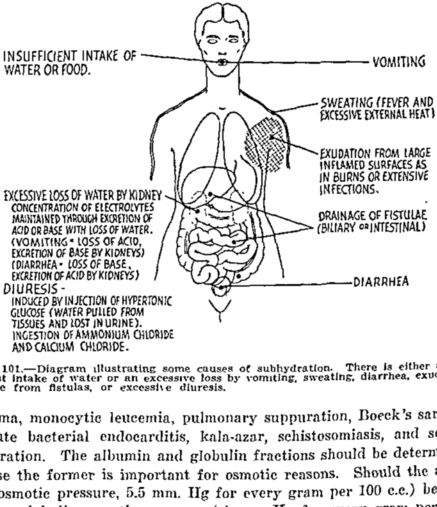

Fig 101.—Diagram illustrating some causes of subhydration. There is either an insufficient intake of water or an excessive loss by vomiting, sweating, diarrhea, exudation, drainage from fistulas, or excessive diuresis.

myeloma, monocytic leucemia, pulmonary suppuration, Boeck's sarcoid, subacute bacterial endocarditis, kala-azar, schistosomiasis, and severe dehydration. The albumin and globulin fractions should be determined because the former is important for osmotic reasons. Should the albumin (osmotic pressure, 5.5 mm. Hg for every gram per 100 c.c.) be low and the globulin osmotic pressure (.4 mm. Hg for every gram per 100 c.c.) be high, anuria and edema may result even though the total protein is normal or above.

Hypoproteinemia and Its Relation to Dehydration.—When plasma proteins are reduced, serious changes may occur. Since most of the plasma protein is synthesized in the liver it is well to classify hypo-

proteinemia under three heads: (1) Prehepatic. There is interference with intake, digestion, or absorption. The liver is normal but the supply is deficient. (2) Hepatic. There is a normal supply but the liver is unable to build protein. (3) Posthepatic. There is an abnormal loss of protein. Since a loss of 1 Gm. of serum albumin means a loss of 30 Gm. of tissue protein, the term protein deficiency may be more appropriate because it is not only blood proteins that become deficient but tissue protein as well. When hypoproteinemia exists, only 3 per cent of ingested nitrogen is fabricated into plasma proteins; the remainder is used to replenish tissue protein. Therefore, in evaluating hypoproteinemia, more than one determination must be made to know the protein reserves.

The causes or pathogenesis of hypoproteinemia are as given in Table X.

TABLE X

I PREHEPATIC	II HEPATIC	III POSTHEPATIC
(a) Nutritional—starvation or malnutrition	(a) Acute yellow atrophy of liver (b) Thyrotoxicosis (c) *Hepatic disease from any cause*	(a) Hemorrhage (b) Shock (c) Burns (d) *Nephrosis* (e) Excessive loss of nitrogen as in thyrotoxicosis and anesthesia (f) Peritonitis

Postoperative hypoproteinemia may be due to all three types; moreover, any type soon involves the others, for a low plasma protein from any cause soon produces liver dysfunction and the reverse is true. The effects of diminished protein are seen clinically in the following:

(1) Shock, which may be due to loss of plasma, loss of nitrogen in urine, decreased ingestion of protein, and inability of liver to synthesize protein.

(2) Suppression of urine due to low osmotic pressure. No fluid is drawn into blood from the tissue spaces where fluid accumulates.

(3) *Hemoconcentration.*

(4) Abdominal distention due to edema of bowel wall and hypomotility. The distention also may be causative due to anoxia caused by interference with respiration and local venous stasis or inflammation. Subcutaneous edema is not always present in edema of the bowel because of the local factors and looseness of tissue in the gastrointestinal tract.

(5) Edema. There is no special level at which this occurs. It varies greatly and is influenced by muscular action, gravity, tissue pressure and venous pressure, hydration (edema would be delayed in dehydration even with low protein), salt and fluid intake, kidney function, and bowel function (diarrhea or vomiting). Usually the edema is peripheral first; then it occurs in the gastrointestinal tract and lungs.

(6) Ascites due to portal obstruction but also hypoalbuminemia (hepatic type). Hydrothorax and hydropericardium.

(7) Delayed and deficient wound healing due to decreased fibroplasia and edema.

(8) Resistance to infection is lowered.

(9) Postoperative asthenia.

(10) Restlessness and irritability.

(11) Decubitus and skin ulcers, also peptic ulcer, which may result from rigid diet with low protein and be improved by high protein diet.

Diagnosis of Hypoproteinemia.—The diagnosis is made by measuring plasma proteins. Several precautions should be taken. In dehydration protein levels may be high yet the total amount of circulating protein low. Total protein may be normal but albumin low. Therefore, a hematocrit should be done and also albumin-globulin determinations. Thus a dehydrated patient may show normal amount of protein. After sufficient fluid physiological saline is given to overcome dehydration, the value of protein goes down and edema may result which is due to hypoproteinemia and not the salt solution.

A hypoproteinemia may exist with normal protein levels in dehydration and there may be no lowering of blood chloride values or elevation of hematocrit, especially if there is a severe anemia. Also there may be a low total volume of protein with plasma protein and blood in normal relations. Blood volume determinations are usually made with T-1824 or Evans' blue dye, and available fluid determinations are made by the sodium-thiocyanate method. In dehydration if the fluid lost has the same electrolyte pattern quantitatively and osmotically as plasma, then the concentration of Na and Cl in the plasma may be normal when the body needs NaCl. Hepatic bile and fluid from the intestinal mucosa contain approximately the same amount of fixed base and chloride as does plasma. Loss of this fluid will cause a reduction of the volume of blood plasma and of interstitial fluid but should not alter the plasma chloride (or bicarbonate) concentrations.

The Prevention and Treatment of Hypoproteinemia.—The average man requires about 3,000 calories a day divided as follows:

Carbohydrate	400 Gm. × 4.1 calories per gram	1640 calories	53%
Fat	115 Gm. × 9.3 calories per gram	1070 calories	35%
Protein	90 Gm. × 4.1 calories per gram	369 calories	12%
		3079 calories	100%

For acute or chronic protein deficiencies, protein should be given by mouth if at all possible. These may be given as concentrates or hydrolysates. Twenty-five per cent of the calories should come from protein, not over 15 per cent from fat, and 60 per cent from carbohydrate. A diet of 150 Gm. of protein a day may be given orally as follows: milk (skimmed), cottage cheese, lean meats including liver and pancreas, egg albumin, soybean. In addition, oral vitamins should be given:

vitamin A, 1,500 units; vitamin D, 1,500 units; ascorbic acid, 225 mg.; thiamine, 9 mg.; riboflavin, 6 mg.; nicotinic acid, 60 mg.

In acute conditions, blood, plasma, and albumin should be given intravenously in combinations to restore blood volume, red blood cell volume, plasma volume, and plasma protein levels to a point where the circulation is adequate. Serum albumin is available in amounts of 25 Gm. This is osmotically equivalent to approximately 500 c.c. of citrated plasma; it is dissolved in 100 c.c. of buffered diluent, giving a 25 per cent solution. It is not often used because it is very expensive and not readily available. If dehydration is present in addition to shock, it is perhaps unwise to use a concentrated solution which must depend on interstitial fluid to restore isotonicity. Since interstitial fluid is depleted, shock and dehydration may be increased. Acid hydrolysate of casein (Parenamine) or enzymatic hydrolysate of casein and pancreas (Amigen) with glucose may be given by vein in *less acute* deficiencies where liver function is normal. However, its use intravenously loses the selective action of the intestine and its utilization is doubtful. A 5 per cent solution of casein hydrolysate in 5 per cent glucose may be used in pre- and post-*hepatic types. Only one-half of the nitrogen in aminoacids is utilized.* The rest is deaminized and used as a source of calories. This mixture is about 25 per cent protein (metabolically) and 75 per cent carbohydrate; that is, in 1,000 c.c. there will be 25 Gm. protein and 50 Gm. carbohydrate. This solution should be given slowly, about 500 c.c. of a 5 per cent solution per hour. But even if given in this way, utilization is doubtful and reactions occur.

Plasma can be used *in chronic deficiencies. However, since* for every gram of plasma protein 30 Gm. of tissue protein are lost or gained, a patient needing 200 Gm. of protein would require 30,000 c.c. of plasma; that is, 7 Gm. per 100 c.c. It is better to use hydrolyzed proteins by mouth. Ascitic fluid and pure amino acids have also been employed. Reactions do occur, with fever, nausea, and thrombosis of the vein in any of the plasma substitutes. Posthepatic types of deficiencies are more *successfully treated than hepatic types. In the hepatic types* plasma substitutes are probably not synthesized. Vitamins may be given intramuscularly: vitamin C, 500 mg.; thiamine, 20 to 40 mg.; riboflavin, 20 to 40 mg.; niacin, 150 mg.

In restoring plasma and blood in acute deficiencies they may be given as fast as the circulation will take them. One thousand cubic centimeters should be given to begin with. The laboratory helps to evaluate the amount needed (hematocrit and plasmaprotein). The best guide, however, is the urine output in amount and specific gravity (if kidneys are normal) which should range from 1.010 to 1.023; also there should be normal body temperature, improved sensorium, slower respiration, increase in blood pressure, slowing of pulse, and sweating.

As a general rule, when capillaries are normal in size and permeability, crystalloids are useful; when dilated and permeable blood and

plasma should be used. In such conditions as severe septicemias where hematocrit and plasma proteins are apt to be low, recovery is helped by transfusions of whole blood and plasma. With widely dilated capillaries these infusions leak out especially the plasma. If by laboratory tests they are found to remain in the blood stream, a better prognosis may be given.

SYMPTOMS OF DEHYDRATION.—Unless ample fluid is given in the acute *water deficiency states*, symptoms of dehydration soon occur. We shall learn in Chapter 13 that with proper treatment the patient may lose up to 40 per cent of the blood volume and recover. However, serious symptoms result if only 10 per cent of the water is lost. This amounts to about 6 per cent of the body weight.

The effects of dehydration are (1) a loss in body weight with great weakness; (2) acidosis causing dyspnea and drowsiness (due to anhydremia which depresses oxidation and causes an accumulation of lactic acid in the tissues); (3) decreased urinary output and in severe degrees with shock, anuria (this also tends to cause acidosis through retention of phosphoric and other acids); (4) increase in nonprotein nitrogen of the blood (insufficient water for kidney excretion, (5) rise in temperature due to decrease in circulating fluid and insufficient fluid for vaporization, also causing anorexia and malaise; (6) thirst, due to insufficient water for salivary gland action and consequently dry mouth, tongue, and throat; (7) dry skin and sunken eyes, due to loss of subcutaneous fluids; the hematocrit reading is elevated, the concentration of plasma protein is greatly increased, and the blood is thick (hemoconcentration); (8) drainage from fistulas (such as drainage from the common duct following choledochostomy) will be greatly reduced. (9) The McClure-Aldrich test will show a shortened absorption time.

DIAGNOSES OF DEGREES OF DEHYDRATION.—Many clinical and laboratory tests *help us to diagnose which factor is at fault.* Vomiting and diarrhea are self-evident, as is also the loss of fluid in proteins from fistulas or large exudating surfaces, as in burns or extensive infections. The quantity of urine and its specific gravity give good evidence of dehydration. Estimations of the total amount and proportions of the plasma protein will often show the cause of the edema. The character of the edematous fluid will also show the nature of the edema: if this fluid is high in protein content, it indicates a plasma edema; if low in protein, a lymphedema. The diagnosis may also be aided by a quantitative estimation of the blood chlorides and the chloride excreted in the urine. Determination of the carbon dioxide combining power will reveal a state of acidosis or alkalosis. Knowing the amount of blood chlorides and the CO_2 combining power, one may estimate the amount of sodium ions in excess of chloride ions, thereby avoiding the time-consuming task of sodium determination. However, the amount of sodium potassium or other cations may be quickly determined by the use of the

Beckman flame spectrophotometer. An increase of potassium in the urine may mean loss of intracellular fluid, and in addition to its indication of cell damage, the potassium itself may be toxic and may be a *factor in the production of shock. The hematocrit* will differentiate between hemorrhage and shock. In hemorrhage there will be a high plasma-low cell ratio; in shock there will be a low plasma-high cell value. Also the size of the cells are indicators of volume of intracellular water; *that is, the mean corpuscular volume. Studies in sodium and potassium* are important because the former is the chief cation of intercellular fluid and the latter is the chief cation of intracellular fluid. The red corpuscle count, hematocrit, and hemoglobin as well as specific gravity of blood and plasma proteins are increased *in dehydration (except in anemia). The* relationship of these factors to each other is constant here.

The McClure-Aldrich test (see Chapter 4) is thought to reveal an impending state of subhydration before symptoms are present. This is due to slight hemoconcentration, which in turn causes a withdrawal of fluid from the intercellular spaces, increasing their avidity for water. This test is not entirely reliable.

The Prevention and Treatment of Dehydration.—We have already noted how the plasma proteins are closely associated with the normal and abnormal movement of water. We have also considered the relationship between water and electrolytes. Let us now review the body's needs for water and the correction of abnormal amounts of water loss.

We have seen that the normal man needs about 5 Gm. of salt a day and in extreme conditions as many as 15 Gm. He also needs approximately 90 Gm. of protein and 400 Gm. of carbohydrate. Fat is not necessary because it is available in the tissues. He also needs about 3,500 c.c. of water a day—2,000 c.c. for vaporization and 1,500 c.c. for the urine. Infants require 2½ to 3 ounces per pound per twenty-four hours. Since the skin, lungs, and gastrointestinal tract take the available interstitial water first, the kidneys may be looked upon as buffer organs working with whatever amounts are left over. With normal kidneys water is easily disposed of and therefore more water may be given safely.

If the patient is losing large amounts of fluid by vomiting, diarrhea, biliary fistula, etc., large quantities of fluid may be necessary. In such conditions one is guided by the amount lost (if this can be estimated), by the urinary output, and by the clinical symptoms and signs of dehydration as well as the laboratory aids.

The clinical signs to watch are: (1) Body temperature and skin—if the temperature is normal and the skin moist, there is enough water for the regulation of vaporization. (2) Amount of urine and its specific gravity and reaction—if normal, this means enough fluid is available for the "buffer" organ and if not too concentrated (over 1025) the tubules have conserved a normal amount of water. (3) Pulse and blood pressure—a rising pulse with fall in blood pressure means a reduced circu-

lating blood volume. (4) *Respiration—if rapid means stagnant anoxemia.* (5) Sensorium—if dull means dehydration and perhaps cerebral anoxia. (6) Edema—with bedfast patients this is often observed first *in the flanks and posterior axilla;* if the patient is sitting up, ankle edema. Many writers contend that one should not wait for edema to prove hypoproteinemia. This is not intended to supplant laboratory tests. However, it is true that laboratory aids frequently reveal normal values when edema is present. If the patient has not received too much sodium (hypernatremia) the presence of edema means hypoproteinemia regardless of tests. The reasons for this have been discussed previously. (7) Thirst is unreliable as a guide because with severe depletion of sodium (as in vomiting) there may be no thirst or oliguria. In starvation thirst is extreme and oliguria is present. (8) Color of face and lips (dusky red) and dry mouth are present in severe dehydration.

Laboratory aids need not be extensive: erythrocyte count, hemoglobin, plasma proteins with albumin, globulin fractions, and hematocrit; occasionally the CO_2 combining power and blood chlorides. The latter shows the amount of sodium ions in excess of chlorine ions and eliminates the necessity for sodium determination. A very useful test to evaluate salt depletion is the urine chloride test (Fantus). It is done as follows:

Urine Chloride Concentration Bedside Test

Materials used

1. Clean test tubes
2. Medicine dropper (standard size)
3. 20 per cent potassium chromate
4. 2.9 per cent silver nitrate
5. Distilled water for rinsing

Technique

10 drops of urine in test tube plus one drop 20 per cent potassium chromate. Then add drops of silver nitrate, drop at a time, shaking until yellow color turns brick red (end point).

Number of drops of silver nitrate equals urine sodium chloride concentration in grams per liter (3 grams per liter per twenty-four hours normal). *Urinary output per twenty-four hours should be about 1,500 c.c.*

Azotemia is a secondary effect and it indicates kidney damage. Therefore, a nonprotein nitrogen determination is indicated.

Methods of Replacing Fluids.—The best method of replacing fluids is by mouth. Where no contraindication is present, such as edema due to low protein or burn shock (see Chapters 6 and 14), thirst is a good indicator of the amount required, and water may be given as desired over and above the minimum requirement.

It is well to remember that water and glucose are absorbed not in the stomach but in the small intestine.

The type of fluid may have to be regulated. Workers in extremely hot temperatures lose chlorides through sweating and will have heat

exhaustion unless they are given sufficient salt with their drinking water. Patients with nephrosis lose so much protein through the kidneys that a high protein diet must accompany liberal amounts of water.

Should a patient be unable to take fluids by mouth, intravenous therapy is best. However, hypodermoclysis is very effective and is particularly useful in those in whom intravenous therapy is difficult (newborn, patients with poor veins, obese patients), in those in whom a sudden increase in blood volume is undesirable (cardiac disease), and in patients whose osmotic equilibrium is difficult to maintain (burns, fistulae in children). *Physiological saline is the safest solution to use. If rapid* absorption is desired, lyophilized hyaluronidase (Hydose—Wyeth) may be added. It is said to liquefy the hyaluronic acid gel present in connective tissues which normally act as a barrier to diffusion. In the average adult 1,000 c.c. are injected (slowly) every 8 hours. Physiological saline is the most useful but may produce so-called salt block if used in excess. Even vomiting causes a loss of only about 5 Gm. of salt per liter. Physiological saline contains about 9 Gm. per liter. Perhaps the best solution to use with saline is 5 per cent glucose in distilled water. This is isotonic and will supply sufficient carbohydrate fuel to prevent acidosis. In cases of intestinal obstruction it is well to alternate or vary the two solutions as required.

Even if water (without salt or glucose) could be absorbed, it would be eliminated by the kidneys without benefit to the body. For example, in intestinal obstruction gastric juice, with its chloride, is lost due to vomiting. Much base is left, which is excreted by the kidneys, with the result that sodium and chloride are depleted in the extracellular fluid. Therefore the need for sodium chloride, and because of local factors and anoxemia a loss of protein occurs which must be corrected.

A study of the blood chlorides and the carbon dioxide combining power aids in the proper evaluation of a possible alkalosis (treated by giving chloride) and acidosis (treated by giving bicarbonate). Ringer's solution or lactated Ringer's solution (Hartmann) is used in dehydration due to diarrhea. In every instance intravenous fluids must be supplemented by blood or plasma transfusion to keep up the normal osmotic index. In severe dehydration potassium as well as sodium must be supplied.

The most practical way to determine the need for transfusion is to evaluate the degree of hemoconcentration. This may be done by determining the hematocrit, the serum proteins, the number of red blood cells, and the hemoglobin.

Types of Solutions Used for Intravenous Therapy in Dehydration.—Physiological saline is .85 per cent. The word "*normal*" saline is frequently used. This is technically not correct. Normal saline is 5.846 per cent. A normal solution contains 1 Gm. equivalent of a particular constituent of the solute in a liter of solution. Equivalent weight is the atomic weight divided by the valence (see Chapter 12). A normal solu-

tion of NaCl = 58.46 Gm. per liter. Physiological or isotonic saline contains 10 per cent more sodium and 50 per cent more chloride than does plasma. The excess chloride is eliminated through the kidneys (if functioning), leaving sodium to combine with bicarbonate. This prevents or alleviates acidosis.

Glucose solutions of 5 per cent are isotonic. Glucose is not an electrolyte and therefore does not dissociate into ions. Sodium chloride does dissociate and exerts a much greater osmotic pressure because each molecule of an electrolyte is split into 2 parts (ions) and each of these exerts its separate pressure effect. Therefore saline has twice as many active particles even though the number of molecules is the same. Dextrose is especially indicated in ketosis.

Sodium racemic lactate. One-sixth molar sodium lactate is isotonic (1 part molar sodium lactate to 5 parts distilled H_2O). Lactate requirements may be calculated if the bicarbonate level in the blood is known. Ten cubic centimeters of solution per kilogram of body weight are required to raise the carbon dioxide content of the blood 10 volumes per cent (Talbott). This solution is useful in acidotic states.

Ringer's solution is useful in diarrheas of children because it contains sodium, calcium, and potassium.

Hypotonic solutions, 0.45 per cent of NaCl or 0.38 per cent NaCl plus 0.11 per cent $NaHCO_3$, are advocated by Coller in postoperative dehydration.

Hypertonic solutions. Glucose, sucrose, salt, or plasma may be used. Dehydration is a definite contraindication to their use because they tend to pull interstitial fluid into the blood stream. *Since interstitial fluid is already depleted, intracellular fluid is moved,* causing damage to tissue cells. Other objections to their use are: thrombosis of veins at site of injection, transient kidney damage, spasm of the duodenum, and sphincter of Oddi. If capillaries are very permeable, the solution may enter tissue spaces damaging cells.

Miscellaneous Data Concerning Intravenous Therapy: In dehydrated patients intravenous fluids cause a prompt rise in cardiac output due chiefly to stroke volume. This is not true of normal subjects.

In cardiac disease the danger of intravenous therapy is not so much the increase in blood volume as in altering the already disturbed chemistry of body fluids, further increasing osmotic derangement. *If fluids are needed, they should be used judiciously.*

There is very little elevation of venous pressure (11 cm. of water) in normal subjects even when 168 c.c. of saline are given intravenously per minute up to 2,000 c.c. There is no increase in heart rate. The peripheral and pulmonary veins and capillaries dilate to *accommodate* the fluid. *If there has been previous hemorrhage or dehydration, there is no rise in venous pressure.*

A good rule to follow: Use intravenous saline cautiously in the presence of alkalosis, hypoproteinemia, anemia, or oliguria. If in doubt,

give isotonic saline by hypodermoclysis; then, if osmotic pressure is at the edema level, the solution will remain under the skin unless given rapidly under excessive pressure (that is, over 35 mm. of mercury). Potassium citrate or chloride may be necessary rather than sodium chloride when there is alkalosis and hypokalemia and hypochloremia.

Chapter 12
ACID-BASE BALANCE

When certain chemical substances are dissolved in water they dissociate into *ions*. These dissociated (ionized) molecules and the undissociated (un-ionized) molecules establish an *equilibrium*. Substances whose molecules dissociate are known as *electrolytes*. Ions which are positively charged are called *cations* (indicated by + sign) and those negatively charged, *anions* (indicated by − sign).

The anode is the positive pole, the cathode is the negative electrode or pole of an electric circle. When a chemical is dissociated, the ions which are given off at the positive pole, although called anions, are negatively charged (−) while those given off at the negative are called cations and are positively charged (+).

Water itself dissociates (slightly) into H^+, which is positive, and OH^-, which is negative. The law of mass action applies in each case. Simply stated, it means that *chemical equilibrium* will be established between the H^+ ions (acid) and the OH^- (alkaline). Water is neutral. When an acid is made with water as a vehicle, no matter how great the preponderance of H^+, there will always be some OH^- present. It is this degree of H^+ concentration over OH^- that determines the alkalinity; if neither predominates, there is neutrality. Thus we see that neutrality does not mean the absence of acid and alkali but enough of each to counterbalance the other. The symbol pH is used by chemists to denote the degree of acidity. When 1 mol of H ion is present in a liter of water, the pH is 0.0.

The logarithm of 1 is zero. The logarithm of 10 is 1 or unity. Any number between 10 and 100 has a common log which lies between 1 and 2, etc.

If a solution contains only 0.1 (or 10^{-1}) mol of H^+, there is less of H^+ and more OH^-; the pH is 1.0 (or the negative logarithm of 0.1). A *less* acid solution thus has a higher pH; a *more* acid solution, a *lower* pH. The relation between pH and the concentrations of hydrogen and hydroxyl ions may be seen in Table XI.

In speaking of solutions and their composition it is necessary to use a term which will serve as a common denominator to express osmotic pressure of the solution. For this reason milliequivalent is employed. This makes it unnecessary to speak in terms of grams, milligrams, and volumes per cent, because regardless of its nature, each milliequivalent has the same osmotic pressure effect. In ionized solution each ion exerts its own milliequivalent. One gram molecule is the molecular weight expressed in grams. The gram molecular weight divided by the valence of the active gram is the gram equivalent weight. Thus sodium = 23 plus

chloride = 35.46. Therefore, the gram molecular weight of sodium chloride is 58.46. The value of the active group is one. Therefore, the number remains the same. That is, the gram weight in this case is equal to the gram molecular weight.

An equivalent weight may be defined as the quotient of the atomic weight of an element divided by its valence or its change in oxidation state. The following is the formula for obtaining the equivalent weight:

$$\frac{\text{Atomic weight}}{\text{Valence}} = \text{Equivalent weight}$$

A normal solution is one that contains one gram equivalent weight per liter. A milliequivalent is 1/1000 of a gram equivalent. A mol is a gram molecule. In a solution it is the molecular weight of the active chemical expressed in grams. A molecular solution is one containing one gram molecular weight per 1,000 c.c. Chemicals act mol for mol or equivalent for equivalent. Therefore, one equivalent is equal to one equivalent and one milliequivalent is equal to one milliequivalent.

The following formula may be used to find milliequivalents per liter:

$$\text{Milliequivalents per liter} = \frac{\text{Milligrams per liter} \times \text{valence}}{\text{Atomic weight}}$$

Examples: Normally there are about 10 mg. of calcium per 100 c.c. of serum. Calcium has an atomic weight of 40.08. Its valence is 2. Thus:

$$\frac{100 \times 2}{40} = 5 \text{ meq.}$$

Potassium is present in the amount of 20 mg. per 100 c.c.; it has an atomic weight of 39.096 (roughly 40). Its valence is 1. The formula is:

$$\frac{200 \times 1}{40} = 5 \text{ meq.}$$

The following is a list of some of the more common milliequivalents. Normal values for electrolytes of human serum and plasma:

BASE—CATIONS			ACID—ANIONS		
Na^+	136-145	meq. per liter	HCO_3^- (vol. % CO_2)	26-28	meq. per liter
K^+	3.5-5.0	meq. per liter	Cl^-	98-106	meq. per liter
Ca^{++}	4.5-5.0	meq. per liter	HPO_4^-	2-3	meq. per liter
Mg^{++}	2-3	meq. per liter	SO_4^-	1.0-1.5	meq. per liter
			Organic acid	5-7	meq. per liter
			Protein	14-19.5	meq. per liter
Total	146-158.0	meq. per liter	Total	146-158	meq. per liter

The following is a list of the inorganic ions and the method of conversion from milligrams per 100 c.c. to milliequivalents:

$Na^{\cdot}$	mg. per 100 c.c. × 10 ÷ 23	HPO_4''	(mg. P) per 100 c.c. × 10 ÷ 31 × 1.8
$K^{\cdot}$	mg. per 100 c.c. × 10 ÷ 39	SO_4''	(mg. S) per 100 c.c. × 10 ÷ 32 × 2
$Ca^{\cdot\cdot}$	mg. per 100 c.c. × 10 ÷ 40 × 2	$H.HCO_3$ and $BHCO_3$	vol. % ÷ 2.22
$Mg^{\cdot\cdot}$	mg. per 100 c.c. × 10 ÷ 24 × 2	Protein	(Gm. per 100 c.c.) × 2.43
Cl'	mg. per 100 c.c. × 10 ÷ 35		

The valency of HPO_4 is taken as 1.8 because, at the normal pH of extracellular fluid, 20 per cent of the concentration of this radical carries one equivalent of base (BH_2PO_4) and 80 per cent two equivalents (B_2HPO_4), B representing univalent base. Base equivalence per unit of (HPO_4) is therefore 0.2 + (0.8 × 2) = 1.8. The double valency sign is to this small extent inaccurate. For all practical purposes, however, the valency is given as 2 instead of 1.8.

Hydrogen Ion Concentration

The reaction of a solution expressed in terms of hydrogen ion concentration may be expressed positively. However, the quantities involved are so small that this would

necessitate using complicated fractions. For example, the hydrogen ion concentration of normal sodium hydroxide amounts to 0.00000000000001. This value may also be expressed as 1×10^{-14}. The symbol $^{-14}$ to the right of the figure 10 is termed the exponent, or index, and means that in order to express the value in the form of a decimal fraction, the figure 1 must be placed 14 places to the right of the decimal point. Another way to express the fraction would be 1/100000000000000. Other examples of this method of expression: 10^{-1} means 0.1 or 1/10; 10^{-2} means 0.01 or 1/100; 10^{-3} means 0.001 or 1/1000, and so on. (Best and Taylor).

In 1909 Sorensen introduced a system of notation by which the common logarithm (that is, the logarithm to the base 10) of the decimal fraction expression the H ion concentration is employed as a positive number. For example, the H ion concentration of serum is 0.0000004 normal. This could be expressed either as 4×10^{-8}N or as $1 \times 10^{-7.4}$N. The latter expression is simplified by omitting the 10 and replacing the minus sign of the exponent by the symbol pH (hydrogen ion exponent). This gives the value as 7.40 which is derived as follows: The log of the figure 4×10^{-8} is 0.6021 which is subtracted from the negative exponent 8, or − 7.40. The minus sign is then omitted.

TABLE XI

THE RELATION OF PH TO THE CONCENTRATION OF HYDROGEN AND HYDROXYL IONS IN A SOLUTION

	pH	mols per L. [H +]	[OH −] mols per L.
	14.0	0.00000000000001	1.0
	13.0	0.0000000000001	0.1
ALKALINITY	12.0	0.000000000001	0.01
	11.0	0.00000000001	0.001
	10.0	0.0000000001	0.0001
	9.0	0.000000001	0.00001
	8.0	0.00000001	0.000001
NEUTRALITY→	7.0	0.0000001	0.0000001
	6.0	0.000001	0.00000001
	5.0	0.00001	0.000000001
ACIDITY	4.0	0.0001	0.0000000001
	3.0	0.001	0.00000000001
	2.0	0.01	0.000000000001
	1.0	0.1	0.0000000000001
	0.0	1.0	0.00000000000001

It is not necessary for practical purposes to be able to compute these values. It is, however, well to remember that since the figures are logarithmic, a *very small number indicates a great change.* A change of 1 unit is a tenfold change; 0.3 change is a doubling or halving (depending upon which direction); 0.1 is 4/5 or 5/4 (a pH of 4.1, for instance, is 4/5 as acid as a pH of 4.0; and a pH of 4.0 is 5/4 more acid than a pH of 4.1).

By consulting Table XI it will be seen that the figures though stated positively are really negative values; therefore, the greater the number, the less acidity.

"The greater the degree of dissociation of acid, the greater will be the H ion concentration and the greater consequently will be its acid nature. Thus HCl, though it contains only one atom of hydrogen in its molecule, undergoes almost complete dissociation and is a stronger acid than H_2CO_3, which has two hydrogen atoms but dissociates to a small extent." (Best and Taylor.) As the H^+ concentration is lowered, the logarithmic figure increases, until at pH 7.0 the solution is neutral, and when the pH is more than 7.0 the solution is alkaline. Since the figures refer to powers of 10, a pH of 5.00 is 10 times more acid than a pH of

6.00, etc. A pH of 11.00 is 1,000 times more alkaline than a pH of 8.00 (that is, the change equals $10^3 = 10 \times 10 \times 10 = 1{,}000$), etc.

The blood is normally slightly alkaline and remains at about pH 7.4 regardless of the fact that acids (phosphoric, sulfuric, hydrochloric, carbonic, and lactic) are continually entering it. Nature guards this pH as rigorously as the osmotic index or the body temperature. This stability is a part of what Cannon terms homeostasis and is in no small measure related to the action of the sympathetic nervous system. This constant pH is maintained through the action of (1) buffer systems of the blood (substances which take up acids or alkalis), (2) excretion of carbon dioxide by the lungs, and (3) excretion of fixed acids or bases by the kidneys.

Buffer systems of the blood are found (Best and Taylor):

I. In the plasma as
   (1) Free acid (carbonic), and acid bound as sodium bicarbonate; that is, the salt of that acid
   (2) Acid and alkaline phosphates of sodium
   (3) Plasma proteins (which behave as acids and combine with base)

II. In the corpuscles (secondary buffers)
   (1) Oxyhemoglobin and reduced hemoglobin (acid) and potassium salt of pigment (alkaline)
   (2) Potassium salts (acid and alkaline) of phosphoric acid

The excretion of carbon dioxide by the lungs and the absorption of oxygen by the blood is accompanied by a chloride bicarbonate shift.

The absorption of oxygen from the alveolar air is the result of diffusion; that is, there is a greater pressure of O_2 in the alveoli of the lung than in the arterial blood. This difference in partial pressures causes oxygen to pass from the alveoli into the plasma in simple solution and then into the red blood cells. The hemoglobin in the blood leaving the lungs is about 95 per cent saturated in the form of oxyhemoglobin. Practically no oxygen is lost from the arterial blood until it reaches the capillaries. The oxygen tension of tissue fluids and cells is low. Therefore oxygen flows from plasma through the capillary wall to the cells. The plasma oxygen tension is thus lowered and oxygen is released from the red blood cells to the plasma. The reverse is true in the tissues where CO_2 tension is higher than in the blood plasma. Accordingly CO_2 enters the plasma. Here it combines with water to form carbonic acid, $H_2O + CO_2 = H_2CO_3$. This is formed in the red blood cells and not the plasma because the former contains a catalytic enzyme, carbonic anhydrase, which starts the process. At the same time oxyhemoglobin becomes reduced. Reduced hemoglobin is a weaker acid than oxyhemoglobin and therefore it gives up its base to the carbonic acid. Most of the base comes from hemoglobin directly or indirectly. Thus potassium bicarbonate and acid hemoglobin are formed.

$$H_2CO_3 + KHb \longrightarrow HHb + KHCO_3.$$

This reaction causes a higher concentration of bicarbonate ions (HCO_3^-) in the cells than in the plasma and therefore two-thirds of these ions or more diffuse out of the corpuscle. The corpuscle membranes are impermeable to the cations calcium, sodium, and potassium as well as the colloidal anions hemoglobin and plasma proteins. Therefore ionic equilibrium between plasma and cell will be disturbed. To adjust this, Cl^- ions diffuse from the plasma into the corpuscles. The HCO_3^- ions which leave the cells combine with the sodium released from chloride to form plasma bicarbonate, and, as we have seen, the chloride ions combine with potassium within the cells. It is the bicar-

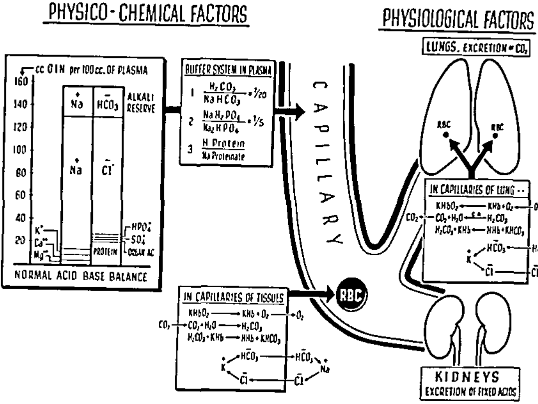

Fig. 102.—Diagram illustrating the maintenance of the pH of the blood. The pH is maintained by physicochemical factors (buffer action) and by physiological factors (regulation of the amount of fixed acids excreted by the kidneys and of the amount of CO_2 eliminated by the lungs). Bicarbonate ions are formed in the erythrocytes, and most of them diffuse out into the plasma, and in return chloride ions diffuse in. Base does not pass because the erythrocytes, though permeable to anions, are impermeable to cations. This mechanism is known as the chloride shift; that is, as bicarbonate goes out, it is accompanied by a shift of chloride into the cell. As blood passes from the arterial to the venous side, carbon dioxide is absorbed and diffuses into the red cell. Some of this is explained on the basis of partial pressures of gases because as the red cell goes to the tissue spaces, it loses some of its oxygen due to the fact that the pressure of oxygen in the tissue spaces is less than that in the red cell. The reverse is true of carbon dioxide. The largest part of freshly generated carbon dioxide is carried by the red blood corpuscles. When the carbon dioxide is absorbed and diffuses into the red cell, a change occurs through the action of carbonic anhydrase, an enzyme, converting the carbon dioxide into carbonic acid (H_2CO_3). The oxyhemoglobin becomes at the same time reduced. Reduced hemoglobin is a much weaker acid than oxyhemoglobin and so gives up its alkali to the carbonic acid. Potassium bicarbonate ($KHCO_3$) and acid hemoglobin (HHb) are thereby formed. The base which previously had been bound to the nondiffusible hemoglobin is now bound as bicarbonate. The concentration of bicarbonate ions (HCO_3^-) in the cell is thereby raised above that in the plasma, and as a result this anion diffuses across the corpuscular membrane. Since the cations cannot diffuse, the ionic equilibrium between the plasma and the interior of the cell will tend to become disturbed. The balance is adjusted by the diffusion of chloride ions (Cl^-) from the plasma into the corpuscles where they combine with the base. The bicarbonate ions (HCO_3^-) which leave the cells combine with the sodium released from chloride to form plasma bicarbonate. As a result of this chemical exchange, the osmotic index within the cells is increased and water, therefore, passes from plasma into the corpuscle, and the latter increases in volume.

At the same time that this shift is going on in the tissue spaces, a similar shift in an opposite direction takes place in the lungs where CO_2 leaves the blood and hemoglobin becomes a much stronger acid as a result of oxygenation. The alkali is released from its combination with chloride and recombines with hemoglobin. The chloride passes out of the cell. The base furnished by hemoglobin thus serves as the chief means by which CO_2 is carried from the tissues to the lungs.

In the diagram this buffer action is illustrated in the tissue spaces as follows: Potassium hemoglobinate when it is reduced gives rise to potassium hemoglobin plus oxygen and oxygen goes to the tissues. At the same time CO_2 enters the red blood cell, it combines with water due to the action of carbonic anhydrase, forming carbonic acid. Carbonic acid plus potassium hemoglobin gives rise to acid hemoglobin plus potassium bicarbonate. The bicarbonate that goes out into the plasma combines with the sodium. The chloride enters the cell and combines with the potassium. In the capillaries of the lung the reverse takes place. Oxygen enters the red blood cell and combines with potassium hemoglobin to form potassium hemoglobinate. At the same time carbonic acid is reduced due to the action of carbonic anhydrase, giving rise to water plus carbon dioxide. The latter is given off. Potassium bicarbonate plus acid hemoglobin gives rise to potassium hemoglobin and carbonic acid. The shift takes place, bicarbonate goes in, chloride goes out. The rest of the buffer system is present in the plasma. The primary buffers consist of (1) carbonic acid (free acids) and acid bound as sodium bicarbonate; the ratio is 1 to 20; $\frac{HHCO_3}{BHCO_3} = \frac{1}{20} = \frac{1.35\ \text{meq./L.}}{27\ \text{meq./L.}} = \frac{3\ \text{vol. \%}}{60\ \text{vol. \%}}$; (2) acid sodium phosphate (a weak acid) and alkaline sodium phosphate (the salt of the buffer pair); ratio about 1 to 5; (3) plasma proteins which at the reaction of the blood behave as acids and so they combine with base. (Diagram showing the normal acid-base balance and chloride shift modified from Best and Taylor.)

bonate shift which makes the "chloride shift." Since blood is a liquid within a liquid, any increase in osmotically active substance within cells will cause water to enter—this occurs in the corpuscle which attracts water from plasma and thereby increases in volume.

In the lungs where CO_2 leaves the blood and hemoglobin becomes a stronger acid (oxyhemoglobin), base is released from chloride and combines with hemoglobin.

$$KHCO_3 + KHb \rightarrow KHb + H_2CO_3.$$

Chloride leaves the cell and bicarbonate enters. The base furnished by hemoglobin is as we have noted the chief means by which CO_2 is carried from tissues to lungs.

The Excretion of Fixed Acids or Bases by the Kidneys.—Normally the glomerular filtrate is neutral, the reaction of bladder urine is acid. By this transformation base is retained and acids are lost. Since the body has only a limited supply of base and cannot make it, all inorganic base lost must be ingested in food. It is therefore vital that base be conserved. Acids are the products of metabolism and are formed in large quantities; therefore they must be eliminated. The formation of ammonia from glutamine, and to a small extent from amino acids in the tubular epithelium, provides another means for the neutralization of acid allowing inorganic base to be returned to the body. When an excess of acid appears in the blood, the kidneys excrete it. If there is an excess of alkali, the kidneys will eliminate base.

A very practical exception to this rule has been reported by Van Slyke and Evans. In extreme dehydration, hypochloremia, and alkalosis the urine may be acid. They found that despite alkalosis (excess, plasma bicarbonate) the urine was pH 5 to 6.4. They attribute this phenomenon to the fact that the body deficiency of sodium salt in severe loss of gastric juice by vomiting is so great that excretion of both NaCl and $NaHCO_3$ is almost completely stopped in the apparent effort to preserve what is left of the body's store of sodium salts. In the absence of bicarbonate in the urine the pH falls toward that of a solution of free H_2CO_3.

Sodium chloride infusions correct the alkalosis and dehydration, replace the lost plasma sodium and chloride, and permit excretion of the excess $NaHCO_3$ which then raises the urine to alkalinity (pH 7.5 to 8.0). Since other base is also lost under such conditions, K, Ca, and Mg should be used in addition to Na.

A summary of the mechanisms regulating the reaction of the blood have been described by Carl Schmidt in the following discussion:

"The fundamental facts are these: In order that the cells of the body may function normally, they must be surrounded by a liquid environment (tissue fluid and lymph) with a reaction slightly on the alkaline side of neutrality. This reaction is maintained constant in spite of wide fluctuations in the amounts of acid and alkali taken into the body with the food and in the amounts of acid produced by the metabolic processes of the body. The factors responsible for this constancy fall into two main groups: (1) *physicochemical*, and (2) *physiological*. The various factors of the two groups cooperate in such ways that a change in one physicochemical factor is compensated ('buffered') by other factors of the same group, and if this proves insufficient physiological factors are brought into activity to restore the reaction of the blood to normal.

"The range of the reaction of the blood serum compatible with life in man appears to be about from pH 7.0 to pH 7.8, but these are the extreme limits encountered in very abnormal conditions. In normal persons the range is much narrower; i.e., the acidity of the serum varies only between pH 7.4 and pH 7.6; under ordinary circumstances the serum remains at about pH 7.4, and if alkalosis is produced (as by overventilation) symptoms of that disturbance (tetany) appear when or before pH 7.6 is attained."

The *physicochemical* factors, Schmidt goes on to say, are the buffers. (Buffers are *substances which prevent changes in the pH of* a solution when an acid or alkali is added.) Chief among the buffers of the blood are the dissolved CO_2 and the basic bicarbonates which are in equilibrium $CO_2/BHCO_3$). The carbon dioxide-bicarbonate buffer system is important quantitatively because it serves as a means of neutralizing

more than 60 per cent of the acids other than carbonic which enter the blood (it cannot of itself neutralize CO_2) and important qualitatively because the CO_2 is volatile and can be eliminated from the lungs (owing to the sensitivity of the respiratory center, an increased tension of CO_2 in the blood increases pulmonary ventilation). "Consequently the amount of bicarbonate in the blood gives a trustworthy picture of the amount of alkali available to neutralize acid, i.e., the alkali reserve. . . .

"The great importance of bicarbonate as a defense against acid depends upon the fact that when another acid is introduced and bicarbonate is decomposed, its acid radical can be eliminated promptly by the lungs. For this reason as much as 80 per cent of the bicarbonate of the blood can be decomposed before severe acid poisoning results. But when the acid is carbonic—as it normally is—hemoglobin is the buffer of paramount importance."

"At the normal plasma pH of 7.40 the proportions of $CO_2/BHCO_3 = 1/20$." If an acid is injected in experimental animals the $BHCO_3$ is reduced, making the blood more acid—the CO_2 tension increases and breathing is stimulated. "CO_2 is thus removed until the ratio $CO_2/BHCO_3$ again becomes 1/20; although the actual amounts of $BHCO_3$ may now be considerably less than before, as long as the ratio remains unchanged the pH is unaltered." *Therefore, changes in acid or alkali content do not cause a change in the pH of the blood, except in cases where such changes are great and prolonged.*

The *physiologic* factors involved in regulating the acid-base balance are *pulmonary ventilation* and *renal excretion.* When acids appear in the blood during violent exercise (lactic acid); in severe diabetes or starvation (beta-hydroxybutyric and aceto acetic acid); or in anoxemia (lactic acid) the alkali reserve is depleted, the H-ion concentration of the blood increases, and the CO_2 tension rises. Breathing is stimulated, the CO_2 tension is reduced, and the ratio $CO_2/BHCO_3$ is restored to 1/20. At the same time the kidney excretes sodium acid phosphate (NaH_2PO_4). If there is an excess of alkali, due to the ingestion of alkali or the loss of acid (as in severe vomiting due to intestinal obstruction or in certain types of diarrhea) there will result a decrease in acidity, breathing will be slowed to allow CO_2 to increase in the blood, and the kidneys will eliminate base (Na_2HPO_4).

If the increase in acid is due to an accumulation of CO_2, bicarbonate is also increased. This is made available by the passage of chloride into the erythrocytes, which in turn yield their bicarbonate ions to the plasma. If the decrease in acid is due primarily to a loss of CO_2 (as at high altitudes, or in hyperpnea from other causes than an increased CO_2 tension in the blood) there is a relative excess of $NaHCO_3$, and this is excreted in part in the urine. *Therefore, an acidosis due primarily to retention of CO_2 is accompanied by an increased bicarbonate, and an alkalosis due to excessive loss of CO_2 is accompanied by a decrease of bicarbonate.*

"The *ammonia mechanism* makes NH_3 available for combination with abnormal acid, as in the acidosis of diabetes, instead of excreting the nitrogen as neutral urea. The ammonia neutralizes acid that would otherwise demand alkali of the blood and the latter is thus spared to some extent. When there is a relative excess of alkali in the blood, ammonia excretion diminishes or ceases and other alkali is excreted instead. This mechanism comes into play very slowly, i.e., after several days of acidosis or alkalosis." Carl F. Schmidt in Macleod's *Physiology in Modern Medicine.*

Acidosis and Alkalosis

Acidosis means excess acid in the body; *alkalosis* signifies excess alkali. Strictly speaking, true acidosis is present only when the blood is less alkaline than normal (pH below 7.4) and alkalosis when the blood is more alkaline than normal (pH above 7.4). Actually, however, there may be sufficient poisoning by acid or alkali excess to produce definite symptoms before the reaction of the blood has changed appreciably.

Therefore, the terms acidosis and alkalosis as we employ them do not necessarily imply a change in pH. As long as the hydrogen ion concentration of the blood remains within normal limits, the acidosis is *compensated*. When the poisoning becomes too severe for the defense mechanisms to compensate and the hydrogen ion concentration changes, the acidosis or alkalosis is *uncompensated* and the condition is usually a very serious one.

If the term acidosis is used to denote a fall in plasma bicarbonate and alkalosis a rise, then they are misleading words because where CO_2 is lost in excess there is a compensatory reduction of $NaHCO_3$ but this is not acidosis. Also if CO_2 is retained as in pneumonia there is a certain amount of compensatory increase in alkali reserve but this is not alkalosis. Therefore two new terms have been introduced: acidemia and alkalemia. Acidemia is a state in which the pH is lowered. Acidosis then is used to denote a lowered alkali reserve **with unaltered pH.** Alkalemia indicates a state in which the pH of the blood is raised. Alkalosis is used to mean an increase in the alkali present with or without a **change in pH.** In the discussion which follows the terms acidosis and acidemia are used to indicate excess acid, whereas the terms alkalosis and alkalemia indicate excess alkali.

Should the pH of the blood reach neutrality (pH 7.0), life would be endangered. However, it may deviate somewhat from 7.4. When the pH rises to 7.6, the patient is said to have an *alkalosis;* a rise to 7.8 would presage death. If the pH falls to 7.2, *acidosis* is said to exist. Since the blood is normally alkaline there is in a normal individual enough alkali available to neutralize considerable amounts of acid. This is called the *alkali reserve* and is used to denote the amount of base in the blood available for neutralization of fixed acids, lactic, hydrochloric, etc. It may be measured by determining the amount of base which is bound as bicarbonate. There is a large quantity of base (sodium, potassium, calcium, and magnesium) which is bound as salts or fixed acids (NaCl) and is not available for the neutralization of acid.

If we can measure the amount of plasma bicarbonate we know how much acid (aside from CO_2) is entering the blood. If acid is increased, there is less bicarbonate; if decreased, there is more. Normal plasma bicarbonate varies between 53 and 75 volumes CO_2 per cent. Free CO_2 is about 1/20 of this, or 2.5 to 3.5 volumes per cent. Normal acid-base balance implies H_2CO_3, $NaHCO_3$, and pH normal.

Clinical states in which there is a disturbance of acid-base balance have been summarized by Van Slyke as follows:

1. *Uncompensated Alkali Excess.*—$NaHCO_3$ is increased without a proportionate rise in H_2CO_3; pH is raised (alkalinity of blood is increased). The ingestion of large quantities of alkali (as in the treatment of peptic ulcer) or the loss of large amounts of hydrochloric acid by vomiting (as in pyloric obstruction) will produce alkalosis or alkalemia; in the former case, by increasing bicarbonate directly, and in the latter

case by increasing them indirectly as a result of lowering the acid. The loss of chlorides due to the persistent vomiting in intestinal obstruction causes the formation of more bicarbonate to maintain the normal osmotic pressure. Therefore the alkalosis is due not only to the loss of HCl (reducing acidity) but also to an increase in bicarbonate. The cell is left without chlorides and therefore water alone (with glucose) could not help without the addition of sodium chloride (see Chapter 11).

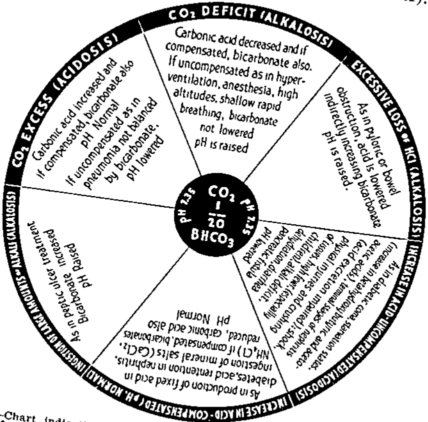

Fig. 103.—Chart indicating clinical causes of acidosis and of alkalosis. When the physiological factors compensate for increase or decrease in acid or base, the pH remains normal. If this mechanism fails, acidosis or alkalosis results.

2. *Compensated alkali excess* may be produced by the same causes as in 1. The bicarbonate is raised, but the carbonic acid also increases; therefore the pH remains normal.

3. *Uncompensated Alkali Deficit.*—The bicarbonates are reduced without a parallel reduction in carbonic acid. The pH is lowered, as in the acidosis of diabetic coma and in starvation states, where there is an increase in beta-hydroxybutyric and aceto-acetic acid, and in the terminal stages of nephritis, where acid exertion is greatly impaired. Shock, physical injuries and crushing of tissues, and high fever (especially in children) also cause an alkali deficit with acidosis.

4. *Compensated Alkali Deficit.*—The bicarbonates are reduced and the carbonic acid also; therefore the pH remains normal. This may occur when there is an abnormal production of fixed acid, as in diabetes, or in

a retention of acid, as in nephritis, or an ingestion of mineral acids or acid-producing salts ($CaCl_2$, NH_4Cl). Compensatory adjustments are seen in the increased acid and ammonia excretion in the urine and the lowered CO_2 tension in alveolar air.

Alkali deficit also results from an increased excretion of base, such as may occur in dehydration (see Chapter 11), pancreatic fistula, diarrhea, etc.

5. *Uncompensated CO_2 Excess.*—Carbonic acid is increased and the increase is not balanced by a proportionate increase of bicarbonate. The pH is lowered (acidosis or "gaseous acidosis" or acidemia). This imbalance *is seen in conditions where CO_2 excretion is interfered with, as in* pneumonia.

6. *Compensated CO_2 Excess.*—H_2CO_3 is increased but there is a proportional rise in $NaHCO_3$; pH is normal. This is seen where there is retention of CO_2 as in emphysema.

7. *Uncompensated CO_2 deficit* may occur as a result of hyperventilation (during anesthesia, in hot baths, at high altitudes, or in shallow rapid breathing from any cause). Carbonic acid is reduced but bicarbonate is not lowered to a corresponding extent; therefore the pH is raised (alkalosis or alkalemia or "gaseous alkalosis").

8. *Compensated CO_2 Deficit.*—The carbonic acid is reduced and also the bicarbonate; therefore, the pH is normal. The causes are the same as mentioned in 7 but less severe. The excretion of bicarbonate by the kidney is much slower than the excretion of CO_2 by the lungs, so the CO_2 deficit is soon compensated. The reduction of CO_2 from rapid or forced breathing has been called acarbia by Henderson. There is some doubt about acarbia being the sole cause of apnea during anesthesia, even though the administration of CO_2 usually corrects the condition. Hyperventilation during anesthesia produces a respiratory alkalosis, CO_2 tension in the arterial blood is reduced, and systolic and diastolic pressures fall somewhat, but this is transient; there may be tetany.

Symptoms and Signs.—The symptoms of acidosis include those of the primary disease causing it and dyspnea. In diabetic acidosis (due to ketone bodies) the dyspnea may be so severe as to resemble the "air hunger" following a severe hemorrhage. In addition there is usually polyuria, excretion of acid (in diabetes, of acetone, as well), and an increase in urinary ammonia. The laboratory shows a decrease in the CO_2 combining power of the blood (that is, a decrease in the CO_2 present as bicarbonate below the normal level of 50 volumes per cent).

One hundred cubic centimeters of arterial blood yields 48 c.c. of CO_2; 45 c.c. of this is in chemical combination (mostly bicarbonate). Venous blood contains about 52 to 70 c.c. of CO_2. By measuring the total CO_2 in a sample of acidified blood and then subtracting the free CO_2 (about 3 volumes per cent), the combined CO_2 is obtained.

Alkalosis would probably show, in addition to the symptoms of the primary disease, a depressed respiration (the alveolar CO_2 tension tends

to rise), excretion of base in the urine, and decrease of urinary ammonia. If the blood becomes definitely alkaline (pH 7.6), tetany may occur. The CO_2 combining power would rise to above 75 volumes per cent (due to an increase in the plasma bicarbonate).

"Air hunger" occurs in various states but is seen principally in diabetic coma and in severe hemorrhage see (Chapter 13). In the former it is due to an acidotic stimulation of the respiratory center chiefly by the acetoacetic acid which also depresses the higher centers of the brain, producing dyspnea with deep labored respirations. In the latter the respiratory center becomes more sensitive because of anemic anoxia: this leads to increased respirations. Cyanosis may be absent in either case (Chapter 19) for it depends on the amount of reduced hemoglobin present in the peripheral vessels.

Treatment of Acidosis and Alkalosis.—The treatment of these conditions is, of course, the elimination of their cause wherever possible. While this is being done, emergency measures are necessary. In pneumonia, oxygen is administered; in diabetes, insulin, etc. The introduction of chloride (as physiological salt solution) in hypochloremic states (such as intestinal obstruction) is a life-saving measure.

Isotonic salt solution is also useful in any acidotic state. It is true that an excess of chloride is present in physiological saline but if the kidneys are normal, this will be eliminated, leaving sodium to combine with carbon dioxide. Severe acidosis may be treated with sodium racemic lactate. One-sixth molar sodium lactate is isotonic, and is made by adding one part of molar sodium lactate solution to five parts of distilled water. About 10 c.c. of solution per kilogram of body weight is required to raise the CO_2 content of the blood 10 volumes per cent (Talbott).

Where much base is lost, as in severe diarrhea, Ringer's solution is perhaps best. In all conditions 5 per cent glucose in distilled water is indicated because of its food value (which counteracts acidosis and ketosis) and its water value (which prevents salt block and dehydration). It may also be given with physiological saline and is especially useful in this way for the treatment of postoperative subhydration and acidosis. Glucose, 0.8 Gm., may be utilized per kilogram per hour. There are only about 100 Gm. of glycogen in the liver of the average man and this would only supply enough sugar for about five hours. In shock and hypoproteinemias of any kind, blood transfusion is the treatment, not only because it restores osmotic pressure, but because the plasma and blood cells contain buffer substances. When large quantities of saline or glucose solutions are used, the osmotic pressure may be decreased greatly. Therefore blood should be used in conjunction with crystalloid solutions. It therefore may be given in any condition. Alkalosis is best treated by physiological saline solution if dehydration is present. Alkalosis caused by excessive loss of CO_2 (from hyperventilation or shallow rapid breathing, as seen during anesthesia) is best treated by the inhalation of CO_2 (7 to 10 per cent or more, depending on the degree of acarbia). A simple practical way to evaluate the need of CO_2 is to give it for one minute. If a seriously high blood CO_2 is present, respiration will be further depressed. If not, it will be stimulated.

The total quantity of body fluid is roughly 70 per cent of body weight. The amount of electrolyte needed to restore a patient to normal may be calculated as follows:

In a man weighing 100 pounds, there is approximately 35,000 c.c. of fluid ($500 \times 70 = 35{,}000$); 20 per cent of this is in the extracellular compartments (15 per cent is interstitial fluid and 5 per cent is blood plasma), making a total of 7,000 c.c. of fluid outside of the cells. Since this intercellular fluid is more readily analyzed than the intracellular component and since it represents the fluid medium in which the cell must live, it is used as an indicator of electrolytic requirements. Thus if the man has a hypokalemia we may arrive at his deficiency by determining the meq./L. of potassium which, let us say, is 3. The normal is about 5 meq./L. of potassium, or a total of 35 meq. There is, therefore, a deficit of 14 meq. in the extracellular compartment, or 2 meq./L. The conversion back to mg. per liter is as follows:

$$\text{meq./L.} = \frac{\text{X} \times \text{Valence}}{\text{atomic wt.}} \text{ or } 2 = \frac{\text{X} \times 1}{39} \text{ or X} = 78$$

Since there were 7 liters of extracellular fluid, there is a deficit of 7 × 78, or 546 mg. of K. The patient should receive about .5 Gm. of KCl by hypodermoclysis in addition to his daily requirement, caused by urinary loss (1.5-2.0 Gm.), or a total of 2.5 Gm. This should be given in sufficient fluid to restore water balance as described in Chapter 11.

This should correct his K deficit provided no further abnormal loss of K occurs. The urinary K should be determined to see whether or not this base is properly conserved by the kidneys.

Chapter 13

HEMORRHAGE

Blood is the medium through which the estimated 23 million millions individual body cells receive their nourishment and oxygen and give off their secretion or excretion and carbon dioxide. It is composed of cells and plasma, 45 per cent of the former and 55 per cent of the latter. Its composition has been likened to the sea water of that early age when terrestrial animals first evolved, and its functions include all of the requirements of a subsisting environment; namely, respiratory, nutritive, excretory, maintenance of water content of the tissues through the capillary walls, regulation of body temperature through its water content and that of the tissues, protection against disease by its antibodies, and regulation of body functions through its connections between organs. These functions are seriously interfered with when there is a great loss of blood.

The cellular part of the blood is made up of erythrocytes, leucocytes, and thrombocytes (red cells, white cells, and platelets). The blood cells are formed principally in the bone marrow, which at any one time may be seen to contain 75 per cent white cells and 25 per cent red cells. The larger production of white cells is necessary because the red cells live from thirty to forty days and are destroyed by wear and tear, whereas the white cells live only a few days and are used up in their constant fight with bacteria and foreign bodies. Vierordt states that there are about twenty-three million millions red blood cells in the huduction of cells by the bone marrow. Acute erythemia is due to the 166, so that the blood contains only about thirty-three thousand million white cells. The erythrocyte contains hemoglobin which transports oxygen in sufficient quantity to maintain life, yet it loses its own nucleus early in its existence, uses no oxygen itself, and has no metabolism of its own. In a sense it is inanimate. A million million (1×10^{12}) red cells are formed daily by 1,400 c.c. of bone marrow largely in the ribs, skull, and vertebrae. During embryonic life they are formed in the liver, spleen, and bone marrow. In the adult they are formed in the bone spaces outside the dilated capillaries. When a sufficient number of cells have developed they break through the capillary walls presumably between the endothelial cells which quickly seal off the openings. White cells get into the blood stream in a similar manner but are capable of ameboid movement and may get into or out of the capillaries on their own power. Over a trillion red cells are destroyed daily. The reticulo-endothelial cells, largely of the spleen, remove them. Incidentally any red cell which is abnormal is removed by the spleen. Therefore, in certain anemias (sickle cell, spherocytosis) where an abnormal cell carries

on the functions of the normal erythrocyte, even though it is in a poor way, it is desirable to retain them; therefore splenectomy may be necessary. With the destruction of the red cells 25 Gm. of hemoglobin is destroyed daily and 100 mg. of iron is released, of which 85 mg. is used again; the rest is replaced by food. Five hundred cubic centimeters of bile, *containing about 350 mg. of bile pigment, is formed and excreted* by the liver.

WHOLE BLOOD = 1/11 th OF BODY WEIGHT

PLASMA ··· 55% by volume of blood

Water · · · · · · · · · · · · · 90 gms. per 100 cc.

Serum Albumin (From Liver) · · 4.1 gms. per 100 cc.

Serum Globulin · · · · · · · · · 2.7 gms. per 100 cc.
(From Liver and Reticuloendothelial Cells)

Fibrinogen (From Liver) · · · · 0.27 gms. per 100 cc.

Other Constituents : Non-protein nitrogen, glucose, chlorides, bicarbonate, magnesium, phosphorus, sodium, potassium, calcium.

CELLS ···· 45% by volume of blood

Red Blood Cells · · · · · · · · 4,500,000 - 5,000,000
(From bone marrow, mostly ribs - live 30-40 days. Destroyed by wear. Contain: Water, 60%, Hemoglobin, 38%, Other Proteins, 1%, also Chlorides, Lecithin, Cholesterol, Urea, Creatinine, Amino-acids.)

White Blood Cells · · · · 5,000 - 10,000 per cubic mm.
(From bone marrow, live only a few days. Lost in defense against bacteria.)

Lymphocytes · · · · · · 15 - 20% of white blood cells
(From lymph nodes and lymphoid tissue. Live 24 hrs. Pass into lumen of bowel.)

Fig. 104.—Composition of blood.

Each cell is about 7/25,000 of an inch in diameter and 2/25,000 of an inch thick and makes about 85 thousand complete trips from lungs to tissues during its life.

The number of red cells is increased in high altitudes, after muscular exercise, sudden increase in environmental temperature, and any condition which lowers the oxygen tension of arterial blood. The increase in the foregoing instances is absolute and comes from a release of red cells

which are stored chiefly in the spleen, and also from an increased production of cells by the bone marrow. Acute erythemia is due to the former, slow increase, to the latter cause.

Relative increase may be caused by a reduction in the amount of plasma or water. (See Chapter 11.)

Pathological conditions causing an *increase* in the number of red cells (polycythemia) are polycythemia vera; lung diseases which interfere with proper oxygenation, such as emphysema, tracheal, or bronchial stenosis, pneumothorax, or pulmonary tuberculosis in some instances; congenital heart disease, especially the tetralogy of Fallot because of pulmonary artery stenosis not in patent ductus; pulmonary arteriosclerosis (pulmonary hypertension), chronic carbon monoxide or chemical poisoning (arsenic, phosphorus, etc.).

Pathological states causing a decrease (anemia) are numerous and often not entirely clear. In general there may be a lack of adequate production (primary anemia) or an increase in destruction over production (secondary anemia). A relative anemia may occur due to increased retention of water in the body (hydremia).

Lymphocytes are formed in lymphoid tissue, chiefly lymph nodes, and live twenty-four hours and most of them are lost in the lumen of the bowel.

Leucocytes are lost in large numbers daily, and in *infections great numbers are produced and lost; often the bone marrow cannot make them fast enough and immature cells are furnished.* If destruction is rapid and in large amounts, pus is formed. Normally the dead leucocytes are removed by the reticulo-endothelial system. (See Chapter 4.)

Blood platelets are derived from the cytoplasm of megakaryocytes which in turn are formed in the bone marrow. They are about one-third the size of a red blood cell and number about 200,000 to 400,000 per cubic millimeter. Their chief function is in connection with blood clotting which will be discussed later in this chapter. They are increased after a meal of meat, during convalescence from infections, in certain allergic conditions, and in myeloid leucemia. *They are decreased in aplastic and pernicious anemia, lymphatic leucemia,* anaphylaxis, and the purpuras (symptomatic as seen in acute infections and idiopathic or purpura hemorrhagica). They are altered in hemophilia.

The fluid part of the blood is composed of plasma which is said to form originally from the secretion or actual solution of cells in the outer layer of the primitive endothelium. Plasma without fibrinogen is called serum. Therefore, plasma proteins include fibrinogen; serum proteins do not. These have been discussed in Chapter 11. *They constitute about 7 to 8 per cent of plasma. Over 90 per cent is water; the rest (about 2 to 3 per cent) is made up of potassium magnesium, etc.*; organic substances other than proteins (nonprotein nitrogenous material such as urea, uric acid, xanthine, hypoxanthine, creatine and creatinine, ammonia, and

amino acids); neutral fats, phospholipids, cholesterol and glucose; *hormones, antibodies, enzymes, amylases, lipases, esterases, proteases, etc.* The average human adult has about 1/11 of the body weight in whole blood and about 1/20 of the total body weight in plasma; this is, 9 and 5 per cent, respectively; that is, 90 c.c. per kilogram (or about 41 c.c. per pound) of body weight in whole blood and 50 c.c. per kilogram (or about 23 c.c. per pound in plasma). Infants have more blood in proportion to body weight.

There is also a relation between blood volume and body surface—it amounts to about 3.3 liters per square meter (Rowntree). This relationship is used on a per cent basis in plasma replacement of burns (Chapter 6). Blood volume may be determined by the dye method, Congo red or Evans blue T-1842. Gregersen developed a method of determining blood volume which is simplified. The steps are as follows: (1) The plasma concentration of the dye T-1824 is measured with the portable decade photometer designed by Nickerson. (2) The total plasma volume is obtained from the dye concentration in a single blood sample drawn ten minnutes after the dye injection. (3) The critical and troublesome procedure of measuring out an exact amount of dye at the time of making the determination is eliminated by using ampules containing a *standard amount of dye solution of known concentration. This also* eliminates all calculations from the determination of total plasma volume. By reference to a chart the plasma volume is obtained directly from the decade photometer reading. The total blood volume is then calculated from the plasma volume and the hematocrit. (4) The hematocrit may be determined with the copper sulfate-specific gravity method instead of with a high-speed centrifuge.

Stroke volume may be ascertained by several methods. In clinical practice the ballistocardiograph is most commonly employed. For more accurate information the Fick principle or the breathing of a foreign gas such as nitrous oxide may be used. The Fick principle is based upon the difference between the oxygen (or CO_2) content of the arterial and that of the venous blood and the total oxygen used (or CO_2 eliminated). By testing alveolar air in the ordinary basal metabolism test, the amount of oxygen consumed per minute is determined. Say it is 250 c.c. The arterial blood contains 20 volumes of oxygen per 100 c.c.; the venous blood, 14 volumes of oxygen per 100 c.c.; therefore, 6 volumes of oxygen is given in the tissues. The cardiac output is $\frac{250}{6} \times 100$; that is, for every 100 c.c. of blood pumped by the heart, 6 c.c. of oxygen were used and 250 c.c. of oxygen were consumed per minute. Therefore, 4,166 c.c. of blood were pumped per minute. If the pulse rate is 72, then the stroke volume would be $\frac{4166}{72}$, or about 60 c.c. per beat.

The difficulty here is that to be accurate the venous blood should come from the right heart because cutaneous veins carry different con-

which are stored chiefly in the spleen, and also from an increased production of cells by the bone marrow. Acute erythemia is due to the former, slow increase, to the latter cause.

Relative increase may be caused by a reduction in the amount of plasma or water. (See Chapter 11.)

Pathological *conditions causing an increase in the number of red* cells (polycythemia) are polycythemia vera; lung diseases which interfere with proper oxygenation, such as emphysema, tracheal, or bronchial stenosis, pneumothorax, or pulmonary tuberculosis in some instances; congenital heart disease, especially the tetralogy of Fallot because of pulmonary artery stenosis not in patent ductus; pulmonary arteriosclerosis (pulmonary hypertension), chronic carbon monoxide or chemical poisoning (arsenic, phosphorus, etc.).

Pathological states causing a decrease (anemia) are numerous and often not entirely clear. In general there may be a lack of adequate production (primary anemia) or an increase in destruction over production (secondary anemia). A relative anemia may occur due to increased retention of water in the body (hydremia).

Lymphocytes are formed in lymphoid tissue, chiefly lymph nodes, and live twenty-four hours and most of them are lost in the lumen of the bowel.

Leucocytes are lost in large numbers daily, and in infections great numbers are produced and lost; often the bone marrow cannot make them fast enough and immature cells are furnished. If destruction is rapid and in large amounts, pus is formed. *Normally the dead leucocytes are* removed by the reticulo-endothelial system. (See Chapter 4.)

Blood platelets are derived from the cytoplasm of megakaryocytes which in turn are formed in the bone marrow. They are about one-third the size of a red blood cell and number about 200,000 to 400,000 per cubic millimeter. Their chief function is in connection with blood clotting which will be discussed later in this chapter. They are increased after a meal of meat, during convalescence from infections, in certain allergic conditions, and in myeloid leucemia. They are decreased in aplastic and pernicious anemia, lymphatic leucemia, anaphylaxis, and the purpuras (symptomatic as seen in acute infections and idiopathic or purpura hemorrhagica). They are altered in hemophilia.

The fluid part of the blood is composed of plasma which is said to form originally from the secretion or actual solution of cells in the outer layer of the primitive endothelium. Plasma without fibrinogen is called serum. Therefore, plasma proteins include fibrinogen; serum proteins do not. These have been discussed in Chapter 11. They constitute about 7 to 8 per cent of plasma. Over 90 per cent is water; the rest (about 2 to 3 per cent) is made up of potassium magnesium, etc.; organic substances other than proteins (nonprotein nitrogenous material such as urea, uric acid, xanthine, hypoxanthine, creatine and creatinin

Angiocardiography synchronized with timing devices and the electrocardiograph easily records circulation time from the vein used, through the right side of the heart, the lungs, the left side of the heart, and the aorta and depicts the relationship with heart cycles as registered in the electrocardiogram (see Chapter 17). *The total circulation time* from the antecubital vein of one arm through the subclavian, vena cava, right heart, lungs, left heart, aorta, subclavian artery, capillary bed, and back to the antecubital vein of the opposite arm is about 21 seconds by the fluorescein method; it varies between 12 and 26 seconds. Pulmonary circulation time (radioactive method) is about 11 seconds (5 to 17 seconds). The volume of blood in the lungs may be calculated by knowing cardiac output per minute and the pulmonary circulation time. The formula is: Cardiac output = 8 per cent total blood volume which is the average quantity of blood in the lungs $\times \dfrac{60}{\text{Pulmonary circulation time}}$

Blood moves at a fairly uniform rate through the pulmonary circuit but varies greatly in the systemic circulation. Circulation time is reduced in hyperthyroidism and in anemia and prolonged in myxedema, polycythemia, cardiac failure, and postoperatively up to 5 per cent by the tenth postoperative day. The latter may be a factor in postoperative phlebothrombosis. The velocity in the larger arteries is about 200 times that of the capillaries. *Blood moves through a closed system* (with the possible exception of the spleen) whose capacity bears a dirct relationship with the volume of blood it contains. Should the volume become greater or smaller, the size of the vascular system varies with it (vasodilation and vasoconstriction). Moreover, the volume is diminished or increased by the compensatory mechanisms to be described. *Should these mechanisms fail, shock follows which tends to conserve* and utilize the volume of blood which remains.

COAGULATION OF BLOOD

Prothrombin + Ca ions + thromboplastin = Thrombin
Thrombin + fibrinogen = Fibrin

Prothrombin is produced chiefly in the liver. Vitamin K is necessary for its formation. Vitamin K (a methyl phytyl naphthaquinone) comes from food (K_1) and from the action of bacterial flora of the large intestines (K_2). Bile is needed for absorption. If there is no bile (as in obstructive jaundice), if coliform bacteria are absent as after succinylsulfathiazole, Sulfathalidine, or streptomycin, administration, if the bowel wall is diseased as in ulcerative colitis and sprue so that absorption cannot occur, or if the liver is diseased so that it cannot use it, a hypoprothrombinemia may occur. Prothrombin is a protein body normally present in concentration of 0.03 per cent or 35 mg. per 100 c.c. of blood. It is constantly being formed and used so that one test is not of

centrations of oxygen. This requires cardiac catheterization (see Chapter 17). Hill has used the hemoglobin content (15 Gm.) to determine arterial blood oxygen and has guessed at venous blood oxygen content based on previous experiments. Calculations would be as follows: 1 Gm. of hemoglobin unites with 1.34 c.c. of oxygen when fully saturated. The O_2 capacity of the blood is 15×1.34, or 20 c.c. Since the arterial blood is about 95 per cent saturated, the O_2 content is about 19 c.c. The amount of oxygen consumed per minute is determined by basal metabolism test. The average venous blood oxygen is known (about 14 volumes of oxygen per 100 c.c.); the amount consumed per minute can be determined as previously described. Say 250 c.c. of oxygen is consumed per minute. The formula would be $\frac{250}{5} \times 100$ or 5,000 c.c. of blood pumped per minute.

The minute volume of the heart normally is between 3,500 to 4,600 c.c. It is fairly constant for a given individual but varies in different people. The minute volume per square meter of body surface is 2,200 c.c.—cardiac index. Therefore, cardiac output is proportional to the basal metabolism which may be predicted along with the former from the surface area. Stroke volume is from 60 to 70 c.c. Cardiac output is increased with strenuous muscular exercise, high environmental temperatures, after a heavy meal, during emotional excitement and pregnancy, and in increased CO_2. It is also increased in abnormal conditions such as hyperthyroidism, anemia, fever, and arteriovenous fistula (although this is questioned by some); it is decreased in cardiac irregularities, organic heart disease, cardiac tamponade, myxedema, pneumothorax, and shock.

CIRCULATION TIME

The time which a red blood corpuscle takes to make the complete round of both the systemic and pulmonary systems is the total circulation time; the pulmonary circuit alone is the pulmonary circulation time. The former may be tested in many ways. If the patient is cooperative, 2½ Gm. of solubule saccharine in 2 c.c. of distilled water may be injected intravenously and the first taste of sweetness is recorded; the same may be done with Decholin and a bitter taste noted. If the patient cannot cooperate, the dye fluorescein may be injected into the arm vein of one side and its arrival at five-second intervals in the corresponding vein of the other arm timed, or histamine may be injected intravenously (0.001 mg. histamine phosphate per kilogram of body weight) and the exact time at which a flushing of the face occurs noted. The pulmonary circulation may be determined by injecting 0.11 mg. of sodium cyanide per kilogram of body weight into the arm vein. Since cyanide stimulates respirations through its action on the carotid sinus, the effect may be recorded by a pneumograph using a stop watch.

Angiocardiography synchronized with timing devices and the electrocardiograph *easily records circulation time from* the vein used, through the right side of the heart, the lungs, the left side of the heart, and the aorta and depicts the relationship with heart cycles as registered in the electrocardiogram (see Chapter 17). The total circulation time from the antecubital vein of one arm through the subclavian, vena cava, right heart, lungs, left heart, aorta, subclavian artery, capillary bed, and back to the antecubital vein of the opposite arm is about 21 seconds by the fluorescein method; it varies between 12 and 26 seconds. Pulmonary circulation time (radioactive method) is about 11 seconds (5 to 17 seconds). The volume of blood in the lungs may be calculated by knowing cardiac output per minute and the pulmonary circulation time. The formula is: Cardiac output = 8 per cent total blood volume which is the average quantity of blood in the lungs $\times \dfrac{60}{\text{Pulmonary circulation time}}$.

Blood moves at a fairly uniform rate through the pulmonary circuit but *varies greatly* in the systemic circulation. Circulation time is reduced in hyperthyroidism and in anemia and prolonged in myxedema, polycythemia, cardiac failure, and postoperatively up to 5 per cent by the tenth postoperative day. The latter may be a factor in postoperative phlebothrombosis. The velocity in the larger arteries is about 200 times that of the capillaries. Blood moves through a closed system (with the possible exception of the spleen) whose capacity bears a diret relationship with the volume of blood it contains. Should the volume *become greater or smaller, the size of the vascular system varies with it* (vasodilation and vasoconstriction). Moreover, the volume is diminished or increased by the compensatory mechanisms to be described. Should these mechanisms fail, shock follows which tends to conserve and utilize the volume of blood which remains.

COAGULATION OF BLOOD

Prothrombin + Ca ions + thromboplastin = Thrombin
Thrombin + fibrinogen = Fibrin

Prothrombin is produced chiefly in the liver. Vitamin K is necessary for its formation. Vitamin K (a methyl phytyl naphthaquinone) comes from food (K_1) and from the action of bacterial flora of the large intestines (K_2). Bile is needed for absorption. If there is no bile (as in obstructive jaundice), if coliform bacteria are absent as after succinylsulfathiazole, Sulfathalidine, or streptomycin, administration, if the bowel wall is diseased as in ulcerative colitis and sprue so that absorption cannot occur, or if the liver is diseased so that it cannot use it, a hypoprothrombinemia may occur. Prothrombin is a protein body normally present in concentration of 0.03 per cent or 35 mg. per 100 c.c. of blood. It is constantly being formed and used so that one test is not of

great value. Consumption or disappearance of prothrombin takes place in the lungs. Platelets undergo disintegration in the capillaries and lungs. Since prothrombin and fibrinogen are constantly produced, it may be assumed that through the action of prothrombin, thromboplastin is converted into fibrin, possibly to protect the integrity of the capillary walls (Howell). The prothrombin response to Vitamin K therapy has been used as a liver function test and as a diagnostic aid in differentiating between intrahepatic and obstructive jaundice. (Chapter 22.)

Thrombokinase or *thromboplastin* is produced from platelets, is also present in all tissues, and is closely allied to cephalin. Thrombokinase alone acts slowly; however, this is not true when it is combined with ionized calcium. Prothrombin is activated by thromboplastin to produce thrombin.

Thrombin (an enzyme) acts on soluble fibrinogen to produce insoluble fibrin which enmeshes blood cells to produce clot. Fibrinogen is produced chiefly in the liver (see Chapter 12).

Blood remains fluid in vessels for two reasons: (1) there is very little thromboplastin present and therefore the active enzyme thrombin is not produced; (2) should thrombin form, a normal antithrombin is present to inactivate it. This antithrombin is thought to be a heparin-albumin compound whose presence is ensured by the constant secretion of heparin into the blood in small amount. Heparin is found in the liver, lung, muscle, and intestinal wall, and, to a lesser extent, in the spleen, heart, and thymus. Heparin is produced in the basophilic mast cells which are found mainly in blood capillaries. Heparin by itself is not an anticoagulant and when added to blood it reacts with some constituent to neutralize thrombin if present or to prevent the conversion of prothrombin to thrombin, or both. In addition, it has anticoagulant properties because it prevents the agglutination of platelets which is the starting point of thrombus formation. Chemically heparin is a mucoitin polysulfuric ester. It is said to act at various sites in the process of coagulation. We have seen that thromboplastinogen plus the activating enzyme from the platelets (thrombokinase) produces thromboplastin. Thromboplastin plus prothrombin plus calcium produces thrombin. (Accelerator globulin is a plasma factor which accelerates the activation of prothrombin in the presence of thromboplastin and calcium ions.) Thrombin plus fibrinogen produces fibrin. Heparin is said to act in the following ways:

1. By the inhibition of platelet agglutination, thereby reducing the amount of thrombokinase.
2. By interfering with the thromboplastin-prothrombin reaction through antithromboplastin and antiprothrombin.
3. By interfering with the action of thrombin and fibrinogen through antithrombin.

Coagulation time must be checked frequently when heparin is being used. The best method for checking *coagulation time is the Lee-White method which is done as follows:*

Puncture the vein with a small needle and syringe and collect 1 c.c. *of blood without using suction. Note the time. Remove the needle from* the syringe and empty the blood into a clean test tube of 8 mm. diameter. Place the tube in a water bath with a temperature of 75° F. or in a room where the temperature is between 65 and 90° F. Tilt the tube at one-minute intervals and note the time when coagulation has taken place, permitting inversion of the tube. The normal by this method is five to ten minutes. After heparin this is prolonged to thirty to forty-five minutes.

The normal coagulation time is about two and one-half to three minutes. If blood is kept constantly stirred, fibrinogen is converted to fibrin which in turn is removed or clings to the stirring rod. That which remains is serum and cells which do not clot. This apparently is the reason that blood in the pleural cavity remains liquid: it is defibrinated and the fibrin adheres to the visceral and parietal pleura.

ABNORMAL STATES

Bleeding tendencies are due to a prolonged clotting or bleeding time. Hemorrhagic diseases due to *coagulation defects* may be outlined as follows:

Thromboplastin Deficiency

Thromboplastin deficiency is the most probable cause of hemophilia (Howell) and is said to be due to an abnormal resistance of the platelets which are unusually sturdy. Since platelets are formed from the cytoplasm of megakaryocytes, these too must be abnormal. Hemophilia is a hereditary disease which is essentially a dysfunction of the megakaryo-*cytes. Bleeding time is normal. Thromboplastin should control the* prolonged coagulation time but does not since it is not available in pure form. Blood and plasma help restore normal coagulation due to the thromboplastin in such blood. We have performed emergency operations on persons with true hemophilia successfully with the aid of plasma and blood transfusions.

Although there is no proof of pseudohemophilia, there are male and female subjects who have a prolonged clotting time which may be dangerous. The condition is congenital and is usually known to the patient. It is not due to any other deficiencies except thromboplastin which is slow in being produced. Perhaps these people have less tough platelets than do those with hemophilia. They respond to such agents as oxalic acid or sodium citrate which may make platelets more vulnerable.

Prothrombin Deficiency

Inadequate supply of vitamin K may give rise to hemorrhagic disease, especially in the newborn. In such cases vitamin K is specific.

Faulty absorption of vitamin K may be due to absence of bile (obstructive jaundice or biliary fistula), severe disease of the intestine preventing absorption (sprue, gastrocolic fistula, ulcerative colitis), or succinylsulfathiazole, Sulfatholidine, or streptomycin, inhibiting the coliform bacteria. Vitamin K and phthiocol (intravenously) are useful.

Prothrombin deficiency may result from inability of liver to utilize vitamin K for synthesis of prothrombin as seen in prolonged obstructive jaundice, severe hepatitis, cirrhosis, hemorrhagic disease of cattle, and drugs such as salicylates and Dicumarol. Vitamin K is useless unless the liver is improved. Intravenous glucose, calcium, and, in cirrhosis, 1.5 to 3 Gm. choline and the same amount of cystine daily, supplemented with 3 to 45 Gm. of Brewer's yeast and a high protein diet, may help improve liver function.

Fibrinogen Deficiency

Fibrinogen deficiency may be acquired due to liver diseases, nutritional deficiency disease, and extensive destruction of bone marrow; it may also be congenital. Blood transfusion is the only treatment except in liver disease (see Coagulation of Blood).

Calcium Deficiency

Calcium deficiency does not cause hemorrhagic disease. Calcium is useful in treatment due to its indirect action on the liver.

Excess of Antithrombin

Excess of antithrombin (heparin) is not present in normal blood; its presence in small amounts does not interfere with clotting mechanisms. Transient bleeding in anaphylactic shock is thought to be due to an outpouring of heparin. No treatment for this is necessary. Also rarely cholinergic drugs such as prostigmine may delay clotting.

Erythroblastosis neonatorum has been discussed in Chapter 10. It is probably due to the passage of anti-Rh agglutinins from the mother, who is usually Rh negative, to the fetus, who is Rh positive. The condition manifests itself clinically in various ways, such as generalized edema (hydrops), icterus, severe degrees of anemia, and hemorrhagic diathesis and may result in stillbirth. Destruction of red cells may be so fast that bile pigment fills the liver and its ducts, producing a jaundice due to hemolysis as well as obstruction by bile pigment. The treatment includes multiple transfusions with Rh-negative blood, vitamin K given intramuscularly, glucose given intravenously, and oxygen by inhalation. It is thus apparent that in this condition any or all of the factors interfering with normal coagulation may be present.

The clotting of blood may be hastened then by correcting factors which are preventing it, if possible. In addition, adrenalin intramuscu-

larly may help (normally shortened clotting time is noted from emotional excitement, muscular exercise, and hemorrhage—probably through the liberation of adrenalin). Thrombin and thromboplastin are useful, especially the newer products. These will be discussed later. Some snake venoms accelerate clotting due to their proteolytic enzyme which converts prothrombin to thrombin.

Prolonged Bleeding Time

Hemorrhagic states due to *prolonged bleeding* time are usually termed *purpura*. Since there are various causes for this disease, it is well to look upon it as a symptom of a disorder of the blood vascular tree because coagulation is normal. Purpuric spots or ecchymoses are seen in acute infections (scarlet fever, smallpox, diphtheria, meningo- and streptococcic septicemia), in scurvy, in leucemias, and various anemias, and in toxic reactions resulting from snake venoms, sulfonamides, etc. In some types there is a degeneration of the capillary wall; in others there is a thrombocytopenia, although low platelet counts are not always present. Perhaps the platelets repair or seal off weak points in capillaries and their reduction leaves wear and tear without restitution. Platelets may be destroyed too rapidly or are not produced in sufficient amounts as seen in aplastic anemia and leucemia.

The *types* of *purpura* are: (1) *Symptomatic* (a) which is not dependent on disturbance of the blood and (b) which is associated with thrombocytopenia. (2) *idiopathic:* (a) primary or anaphylactoid; in this group are Schönlein's disease (with joint manifestations) and Henoch's (with intestinal crisis). There is no specific treatment for these groups. If the *cause* can be found, it should be eliminated. (b) Thrombocytopenic (idiopathic purpura hemorrhagica, Werlhof's disease); treatment is splenectomy (see Chapter 22). (3) *Purpura fulminans*—a fetal disease with normal platelet count. The cause is unknown. An anticoagulant resembling heparin has been found in the blood of dogs that had hemorrhagic tendencies after prolonged exposure to x-ray. This bleeding may be prevented and temporarily stopped by the intravenous use of protamine sulfate or toluidine blue. This is thought to be due to the ability of these substances to render heparin inactive. Patients with thrombopenic purpura have an increase in a heparin-like substance and toluidine blue or protamine sulfate helps arrest bleeding in thrombopenic purpura. Titration of the patient's blood may reveal the presence of a heparin-like substance. These antiheparin drugs may then be used in preparation for splenectomy, in cases of acute bone marrow suppression, in leucemias, and in patients who have received too much heparin.

CLOTTING TENDENCIES

Intravascular clotting is discussed in Chapters 5 and 17 under thrombosis and Embolism. It should be reviewed in this chapter because of the use of anticoagulants and their relation to hemorrhage. Experi-

Prothrombin Deficiency

Inadequate supply of vitamin K may give rise to hemorrhagic disease, especially in the newborn. In such cases vitamin K is specific.

Faulty absorption of vitamin K may be due to absence of bile (obstructive jaundice or biliary fistula), severe disease of the intestine preventing absorption (sprue, gastrocolic fistula, ulcerative colitis), or succinylsulfathiazole, Sulfatholidine, or streptomycin, inhibiting the coliform bacteria. Vitamin K and phthiocol (intravenously) are useful.

Prothrombin deficiency may result from inability of liver to utilize vitamin K for synthesis of prothrombin as seen in prolonged obstructive jaundice, severe hepatitis, cirrhosis, hemorrhagic disease of cattle, and drugs such as salicylates and Dicumarol. Vitamin K is useless unless the liver is improved. Intravenous glucose, calcium, and, in cirrhosis, 1.5 to 3 Gm. choline and the same amount of cystine daily, supplemented with 3 to 45 Gm. of Brewer's yeast and a high protein diet, may help improve liver function.

Fibrinogen Deficiency

Fibrinogen deficiency may be acquired due to liver diseases, nutritional deficiency disease, and extensive destruction of bone marrow; it may also be congenital. Blood transfusion is the only treatment except in liver disease (see Coagulation of Blood).

Calcium Deficiency

Calcium deficiency does not cause hemorrhagic disease. Calcium is useful in treatment due to its indirect action on the liver.

Excess of Antithrombin

Excess of antithrombin (heparin) is not present in normal blood; its presence in small amounts does not interfere with clotting mechanisms. Transient bleeding in anaphylactic shock is thought to be due to an outpouring of heparin. No treatment for this is necessary. Also rarely cholinergic drugs such as prostigmine may delay clotting.

Erythroblastosis neonatorum has been discussed in Chapter 10. It is probably due to the passage of anti-Rh agglutinins from the mother, who is usually Rh negative, to the fetus, who is Rh positive. The condition manifests itself clinically in various ways, such as generalized edema (hydrops), icterus, severe degrees of anemia, and hemorrhagic diathesis and may result in stillbirth. Destruction of red cells may be so fast that bile pigment fills the liver and its ducts, producing a jaundice due to hemolysis as well as obstruction by bile pigment. The treatment includes multiple transfusions with Rh-negative blood, vitamin K given intramuscularly, glucose given intravenously, and oxygen by inhalation. It is thus apparent that in this condition any or all of the factors interfering with normal coagulation may be present.

The clotting of blood may be hastened then by correcting factors which are preventing it, if possible. In addition, adrenalin intramuscu-

larly may help (normally shortened clotting time is noted from emotional excitement, muscular exercise, and hemorrhage—probably through the liberation of adrenalin). Thrombin and thromboplastin are useful, especially the newer products. These will be discussed later. Some snake venoms accelerate clotting due to their proteolytic enzyme which converts prothrombin to thrombin.

Prolonged Bleeding Time

Hemorrhagic states due to *prolonged bleeding* time are usually termed *purpura*. Since there are various causes for this disease, it is well to look upon it as a symptom of a disorder of the blood vascular tree because coagulation is normal. Purpuric spots or ecchymoses are seen in acute infections (scarlet fever, smallpox, diphtheria, meningo- and streptococcic septicemia), in scurvy, in leucemias, and various anemias, and in toxic reactions resulting from snake venoms, sulfonamides, etc. In some types there is a degeneration of the capillary wall; in others there is a thrombocytopenia, although low platelet counts are not always present. Fibrinogen Deficiency

Fibrinogen deficiency may be acquired due to liver diseases, nutritional deficiency disease, and extensive destruction of bone marrow; it may also be congenital. Blood transfusion is the only treatment except in liver disease (see Coagulation of Blood).

Calcium Deficiency

Calcium deficiency does not cause hemorrhagic disease. Calcium is useful in treatment due to its indirect action on the liver.

Excess of Antithrombin

Excess of antithrombin (heparin) is not present in normal blood; its presence in small amounts does not interfere with clotting mechanisms. Transient bleeding in anaphylactic shock is thought to be due to an outpouring of heparin. No treatment for this is necessary. Also rarely cholinergic drugs such as prostigmine may delay clotting.

Erythroblastosis neonatorum has been discussed in Chapter 10. It is probably due to the passage of anti-Rh agglutinins from the mother, who is usually Rh negative, to the fetus, who is Rh positive. The condition manifests itself clinically in various ways, such as generalized edema (hydrops), icterus, severe degrees of anemia, and hemorrhagic diathesis and may result in stillbirth. Destruction of red cells may be so fast that bile pigment fills the liver and its ducts, producing a jaundice due to hemolysis as well as obstruction by bile pigment. The treatment includes multiple transfusions with Rh-negative blood, vitamin K given intramuscularly, glucose given intravenously, and oxygen by inhalation. It is thus apparent that in this condition any or all of the factors interfering with normal coagulation may be present.

The clotting of blood may be hastened then by correcting factors which are preventing it, if possible. In addition, adrenalin intramuscu-

lar surgery to prevent thrombosis after injury of blood vessels, in trans-*plantation of organs, in exchange transfusion,* in coronary thrombosis produced by sclerosing agent, and in the prevention of peritoneal adhesion. Clinically it has been used in peripheral thrombophlebitis and phlebothrombosis, pulmonary embolism, mesenteric thrombosis, coronary thrombosis, cerebral thrombosis, thrombosis of the central vein of the retina, vascular surgery, postoperative prophylaxis against bacterial endocarditis (with penicillin), and in the laboratory for the Wassermann iso-agglutination and other tests. Heparin is best administered intravenously although it may be given by subcutaneous injection. The smallest effective dose to maintain blood coagulation at from fifteen to thirty minutes is desirable. Heparin has no effects on blood clots but will prevent further thrombi from forming (propagation thrombi). Usually 1,000 to 2,000 units per hour or from 10 to 20 mg. per 100 c.c. of fluid by venoclysis will be necessary. Heparin may be given by subcutaneous injection using Pitkin's menstruum which releases water-soluble drugs slowly. It is composed of 18 per cent gelatin, 8 per cent dextrose, 1 to 1.5 per cent acetic acid, and distilled water sufficient to make 100 per cent. *Heparin, 100 to 200 mg., is added to this menstruum with or with-*out the vasoconstrictors, 10 mg. of ephedrine and 1 mg. epinephrine. This mixture is available in 1 or 2 c.c. ampules. Pitkin's menstruum is effective but painful. Patients under 150 pounds (68 kg.) get 1 c.c. containing 100 mg. Heavier individuals get double the dose. Subsequent doses depend on the response. Prothrombin time as well as coagulation time should be taken every twelve hours. If the former is prolonged, vitamin K may be necessary after the use of Dicumarol, since it takes Dicumarol two to five days to act. This drug may be given at the same time that the heparin solution is injected. The latter takes only one and one-half to two hours to act and prolongs coagulation time for twenty-four to forty-eight hours if given without vasoconstrictors. If given with them, the action of heparin lasts about sixty hours. A Howell unit is defined as the quantity of heparin which will prevent the clotting of 1 c.c. of cat's blood kept cold for twenty-four hours. For transfusion the donor is given ¾ to 1 mg. per kilogram of body weight. After heparin is discontinued, the coagulation time returns to normal in a few hours. *Protamine* given intravenously hastens its return to normal because it is a strongly basic protein and heparin breaks its combination with the albumin factor in favor of the more strongly basic protein protamine, thus releasing thrombin. Whole blood or plasma may also be used for this purpose.

Some people are sensitive to heparin, others are resistant. The latter are seen in (a) early postoperative period, (b) following cardiovascular accidents (coronary thrombosis, thrombosis, cerebral hemorrhage), (c) Buerger's disease.

Heparin is available in two types: the aqueous solution which may be used intravenously and which produces a high concentration but has

mentally coagulation may be produced by (1) by the injection of thrombin (this is *transient and may be followed by* a negative or prolonged coagulation time); (2) by the injection of *thrombokinase (from lung,* thymus, and lymph nodes); if continued the fibrinogen is used up and clotting is delayed; (3) by injury of the vessel. Clinically it is seen due to (1) injury to the vessel: (a) *outside* the vessel at surgery, during forceps delivery, by inflammation around the artery or vein, and by new growth; (b) *inside* the vessel by trauma produced by hypertonic solutions or the *needle in continuous venoclysis, by infections* such as pneumonia, etc., or by toxins as in eclampsia and burns; (2) changes in the rate of flow; this is especially serious because it is silent without symptoms (phlebothrombosis) and normally occurs in the veins of the lower legs following complete immobilization; (3) changes in the density of the blood in dehydration, starvation, etc.; (4) chemical changes as in anoxemia; *from large doses of digitalis and adrenalin through nervous stimulation or injection.*

Anticoagulants

Blood *clotting is inhibited by* : (1) *Cold due to its effect on clotting* enzymes. Therefore, stored blood is kept at 5 to 10° C.; this also retards bacterial growth if there is contamination. Ultimately the blood clots. Cold decreases bleeding on the body surface due to vasoconstriction. (2) Avoidance of contact between blood and injured tissues or rough surface which prevents clotting for a time. The well-known *fact that a wound made by a sharp instrument bleeds more than one* by a blunt force provides for less platelet disintegration in the former and more in the latter. The old Kimpton-Brown method of transfusion was accomplished by using paraffinized glass cylinders to avoid a rough surface. (3) Decalcification, where the addition of sodium oxalate (or potassium or magnesium) or a fluoride (0.1 per cent) *to blood will prevent clotting.* Calcium oxalate is formed in the former instance. Sodium citrate also prevents clotting in vitro (not in vivo) by forming calcium sodium citrate. If calcium chloride is added, the blood clots again; also the addition of thrombin or thromboplastin will do this. (4) Neutral salts such as magnesium sulfate, 27 per cent solution, *mixed 1 part to 4 of blood;* also sodium sulfate, 10 per cent solution, mixed with equal parts of blood. (5) Azo dyes (Chicago blue, 6 B, trypan red, trypan blue, etc.). (6) Biological products: (a) hirudin from leeches, (b) snake venoms, (c) peptone solution, (d) cysteine, (e) heparin, (f) Dicumarol.

Heparin and Dicumarol have important *clinical applications.*

Heparin.—The nature and source of *heparin has been briefly* discussed. Its *action* is based on an inhibitory effect on prothrombin, or the first stage of coagulation, and on thrombin to prevent the second stage. The presence of a component of the serum-albumin fraction is necessary before heparin can assert its action. Heparin and thrombokinase are antagonistic. *Heparin has been used experimentally in* vascu-

hours, but if the fortified heparin has been used, it takes approximately twenty-four to forty-eight hours for the coagulation time to again become normal.

Heparin may be used in doses sufficient to prolong coagulation up to sixty minutes; however, usually thirty to forty-five minutes is considered adequate. It, of course, should not be used in blood dyscrasias or recent *operations on the spinal cord where bleeding might result in very* serious consequences or before surgery. In cases with ulcerative lesions or open wounds or where drainage tubes are used, as in the renal pelvis or the common bile duct, or with indwelling catheters or tubes in the nose and mouth, the risk of bleeding is great and, therefore, heparin should be used with extreme caution. Since the effect of heparin is prompt and that of Dicumarol is delayed, some surgeons prefer to use heparin to get the immediate effect and then fortified heparin or Dicumarol to get a delayed effect. As we shall see, Dicumarol is a drug with considerable danger because of its toxic action on the liver; therefore, the trend at present is to rely more upon heparin than upon Dicumarol. However, the ease of administration of Dicumarol has made it the drug of choice where treatment must be continued over a long period of time.

Dicumarol.—AP or antiprothrombin was the name given by Swedish biochemists for 3,3′-methylene bis (4-hydroxycoumarin) or Dicumarol because it was thought to inactivate or destroy prothrombin. By studying the hemorrhagic disease in cattle resulting from the ingestion of spoiled sweet clover, the active principle Dicumarol has been isolated. Its anticoagulant effect is due to a depression of synthesis of prothrombin *rather than a direct effect on this substance. Although there is no* destruction of liver tissue or reduction in any other function, there is an effect on prothrombin production. The return of prothrombin levels to normal may be speeded by the administration of vitamin K_1 oxide. This is due to either a neutralization of the toxin or the synthesis of prothrombin *in the presence of excess vitamin K. Salicylates* may cause hypoprothrombinemia and this can be prevented or counteracted by the administration of synthetic vitamin K. Dicumerol is useful in many of the states in which heparin is employed. Thus it may be employed prophylactically after operations likely to be followed by thrombosis and embolism such as splenectomy and pelvic operations; in surgery of the blood vessels (traumatic injuries, removal of the thrombus or embolus); as a therapeutic measure in phlebothrombosis, phlebitis, and thrombophlebitis in the extremities; thrombosis or embolism in pulmonary vessels, coronaries, and mesenterics; also in blood transfusion and laboratory work. Its great advantage over heparin is its ease of administration. It should not be used in the presence of liver disease. The dose is usually 200 to 300 mg. daily until the prothrombin time has reached 35 seconds, and then 50 mg. daily thereafter. After discontinuation the prothrombin time may be prolonged for two to three days. Heparin and Dicumarol may be used simultaneously.

a transient effect and the so-called fortified heparin which is procurable as Heparin Pitkin Menstruum or Depo-heparin sodium which is made by Upjohn and which is a gelatin fortified compound. This gelatin compound is also further fortified with ephedrine and epinephrine to produce vasoconstriction and thereby to decrease further its rate of absorption. By so doing the effect may be prolonged to forty to forty-five hours. When Heparin is injected very little is found in the urine and practically none in the feces; therefore, most of it is destroyed in the body. Heparin is not toxic, except that it prevents the coagulation of blood and, therefore, is dangerous insofar as it may cause bleeding. The sodium salt of heparin in the aqueous solution (Upjohn) or Liquaemin Sodium (Organon) is available in various concentrations—10 mg. per cubic centimeter and 100 mg. per cubic centimeter are the most common methods of preparing it. These preparations are used for the intravenous route of administration. However, the 100 mg. per cubic centimeter concentration is suitable for the intramuscular route. The dose for the intravenous route, so-called intermittent intravenous medication, is 50 to 100 mg. of heparin every four to six hours. The continuous intravenous drip method which is used as a rule only when clotting time must be greatly prolonged is employed as follows: about 100 to 200 mg. of heparin are introduced in a liter of 5 per cent glucose solution in distilled water or in physiological saline solution. Usually 20 to 25 drops per minute are given. The intermittent intramuscular use of heparin in the aqueous solution is given approximately 1 mg. of heparin per pound of body weight initially and thereafter 0.5 to 0.7 mg. per pound of body weight every eight hours. The heparin sodium in the gelatin dextrose medium known as Depo-heparin sodium (Upjohn) is a product each cubic centimeter of which contains 200 mg. of heparin sodium. Four hundred milligrams of this drug are given, 200 mg. (that is, 1 c.c.) without vasoconstrictors and 200 mg. (1 c.c.) with vasoconstrictors. A dose of 400 mg. ordinarily produces a delay in clotting time for about forty-eight hours. When the drug is used by continuous intravenous drip the coagulation time must be determined at frequent intervals. It is desirable to determine it every eight to twelve hours. When it is given intramuscularly or when the fortified heparin solutions are used, it may be checked daily. Heparin is given subcutaneously so that if the absorption rate will be diminished, cold may be applied and thereby further aid in the vasoconstriction and prevent rapid absorption. It is recommended that it be given in the outer side of the thigh where blood vessels are sparse. If the coagulation time is too much prolonged, that is, more than thirty to forty minutes, it may be inactivated by the use of protamine, giving 1 c.c. for every 1 c.c. of heparin that has been used, or fresh blood transfusion may be employed. Following the use of aqueous heparin either intravenously or intramuscularly the coagulation time will return to normal in from two to eight

1. To curtail further bleeding:

Fall in blood pressure. This is the direct result of the loss in blood volume. Normally the blood pressure is due to the pumping action of the heart, peripheral resistance, and quantity of blood in the arterial system, viscosity of blood, and elasticity of the arterial walls. When the quantity of blood is reduced, the carotid sinus reflex causes vasoconstriction and cardio-acceleration. Perhaps the carotid body is stimulated also due to anoxemia which occurs. Marey's law states that the pulse rate is inversely related to the arterial pressure; that is, with a rise in blood pressure, it is slower and with a fall it is faster. This may occur by way of the aortic arch, afferent vagal, or by way of the sinus nerve.

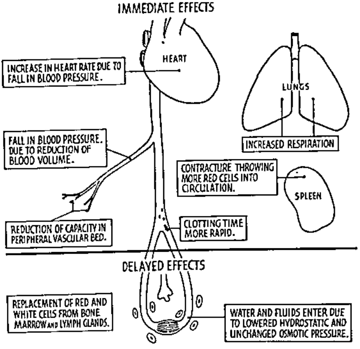

Fig 105.—Diagram illustrating the immediate and late effects of hemorrhage. The reduction of blood volume causes a fall in blood pressure. To compensate for this and to provide the vital centers with blood, peripheral vessels are constricted and the heart beats faster in an attempt to prevent a stagnant anoxia. The respiratory center is stimulated (due to cerebral anemia), and respirations are increased in rate and depth (air hunger). The clotting time decreases the fall in blood pressure, aiding this process. The spleen contracts, forcing more blood into the circulation. Fluid is drawn into the blood stream and after three to four hours causes great dilution. Replacement of cells is complete usually in a week. This varies with the amount of bleeding and the reaction of the patient's bone marrow

The Bainbridge reflex is described as an increase in heart rate caused by a rise in pressure of blood entering the right auricle. More will be said of these mechanics in Chapters 14, 17, and 18. However, the physiological effects rarely behave as single reactions but are multiple and complex The final result may be a temporary *increase* in blood pressure with a *slow pulse* early in hemorrhage. Later blood pressure falls but will rise again at short intervals. The fall in pressure is advantageous for it helps to curtail further bleeding. This is noteworthy during surgery

PHYSIOLOGICAL EFFECTS OF BLOOD LOSS

Blood and oxygen are absolutely essential to life. Deprivation of either constitutes the only real emergency. When more than 40 per cent of the blood volume is lost, the body is unable to repair the loss without the aid of transfusion, and the patient will usually die if this is not instituted. It is said that 500 c.c. of blood in a healthy adult will be replaced in an hour. Blood counts if made immediately after hemorrhage will be normal; soon, however, water is attracted to swell the depleted blood volume and the dilution makes the cell count and the hemoglobin concentration lower. Therefore, one cannot depend upon these counts for reliable information concerning the extent of the hemorrhage when they are made within one to two hours after severe bleeding.

When a man loses 500 c.c. of blood, he also loses 75 Gm. of hemoglobin and about 10 Gm. of plasma protein, or a total of 94 Gm. of protein if hemoglobin is taken as 100 per cent protein. Plasma protein may be regenerated at the rate of 1.3 to 11 Gm. per kilogram per day in the dog. If the same were true in a man weighing 60 kilograms he should be able to synthesize 78 to 660 Gm. of plasma protein a day, or the quivalent of 1,150 to 9,500 c.c. of plasma a day. Plasma proteins are not returned to the blood as fast as cells. The latter probably come from stores (spleen, some in liver and bone marrow). Protein is returned by way of the lymphatics from capillary filtrate and also by mobilization of proteins from depots (see Chapter 12). There is an increase in protein concentration in thoracic duct lymph following hemorrhage but not as much as after traumatic shock. It has been said that 20 per cent of the blood volume may be lost and it will be restored in seven to eight hours. Plasma protein will be slower to return. If thirty per cent is lost, shock usually develops, though not invariably. Shock slows up the process of blood volume restoration. Blood donors giving 500 c.c. of blood take about forty-three days to regenerate hemoglobin; this may be shortened by oral administration of iron.

The foregoing discussion illustrates how labile are the compensatory mechanisms and how unpredictable the effects of hemorrhage, when not massive. Even if blood is restored by transfusion, a patient may die if anemic anoxemia has so damaged capillaries and vital cells that irreversible changes are present. Thus the time element, the amount of blood lost, and the rapidity of its loss are important factors. More important is the ability of compensatory mechanisms to counterbalance the effects of hemorrhage. Let us now consider the early and later adjustments which occur.

Early Adjustments.—As a result of the loss of blood volume, physiological mechanisms attempt to curtail further bleeding, supply oxygen to the tissues, increase the blood volume by throwing in reserves, and contract the vascular bed to lessen the disproportion between circulating volume and vascular area, thereby avoiding shock.

1. To curtail further bleeding:

Fall in blood pressure. This is the direct result of the loss in blood volume. Normally the blood pressure is due to the pumping action of the heart, peripheral resistance, and quantity of blood in the arterial system, viscosity of blood, and elasticity of the arterial walls. When the quantity of blood is reduced, the carotid sinus reflex causes vasoconstriction and cardio-acceleration. Perhaps the carotid body is stimulated also due to anoxemia which occurs. Marey's law states that the pulse rate is inversely related to the arterial pressure; *that is, with a rise in* blood pressure, it is slower and with a fall it is faster. This may occur by way of the aortic arch, afferent vagal, or by way of the sinus nerve.

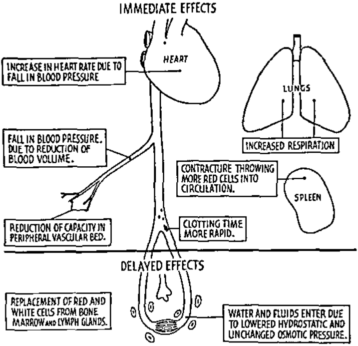

Fig 105.—Diagram illustrating the immediate and late effects of hemorrhage. The reduction of blood volume causes a fall in blood pressure. To compensate for this and to provide the vital centers with blood, peripheral vessels are constricted and the heart beats faster in an attempt to prevent a stagnant anoxia. The respiratory center is stimulated (due to cerebral anemia), and respirations are increased in rate and depth (air hunger). The clotting time decreases the fall in blood pressure, aiding this process. The spleen contracts, forcing more blood into the circulation. Fluid is drawn into the blood stream and after three to four hours causes great dilution. Replacement of cells is complete usually in a week. This varies with the amount of bleeding and the reaction of the patient's bone marrow

The Bainbridge reflex is described as an increase in heart rate caused by a rise in pressure of blood entering the right auricle. *More will be said* of these mechanics in Chapters 14, 17, and 18. However, the physiological effects rarely behave as single reactions but are multiple and complex. The final result may be a temporary *increase* in blood pressure with a *slow pulse* early in hemorrhage. Later blood pressure falls but will rise again at short intervals. The fall in pressure is advantageous for it helps to curtail further bleeding. This is noteworthy during surgery

for the arrest of hemorrhage due to trauma, or where the operation is accompanied by the loss of large amounts of blood. Small bleeders are often overlooked. Later, after operation, as blood and plasma are given, these may be troublesome, even dangerous. For this reason restoration of blood volume should be synchronous with its depletion. A persistent fall in blood pressure is the most reliable sign of concealed bleeding, although it should be stated that blood pressures as low as 30 systolic are tolerated for hours with recovery. This is not true in traumatic shock; and hemorrhage in patients with shock is disastrous.

Clotting of blood is favored by the lowered pressure and trauma at the site of injury, resulting in an increase in thromboplastin. Clotting time is more rapid in severe hemorrhage.

2. *To supply oxygen to the tissues:*

Increase in heart rate. This will be more fully discussed under the subject of shock (Chapter 14). Cardiac output is only slightly diminished after a loss of 500 c.c. of blood but is greatly diminished after the loss of a liter and during syncopal attacks as determined by the ballistocardiograms. The acceleration of pulse may not occur after hemorrhage with a patient lying quietly but should he move about or try to rise, it becomes rapid and the blood pressure falls. Usually a rapid pulse is an early sign in concealed hemorrhage and is brought about through carotid sinus and aortic reflexes which are initiated by the fall in blood pressure. This is an attempt by nature to increase the rate of blood flow to compensate for the blood's diminished oxygen-carrying power. It is noteworthy that during the syncopal attacks there may be a bradycardia which occurs with vasoconstriction; this is transient and with signs of collapse comes the rapid pulse rate.

Increased respiration is designed to relieve the anemic anoxemia. It is caused by the anoxia of the chemoreceptors of the aortic and carotid bodies which are deprived of sufficient oxygn due to diminished blood flow. At first there is an increase in the rate and depth of breathing; later, if the hemorrhage is profound, sighing respiration occurs (air hunger); still later this may become Cheyne-Stokes in type, gasping respirations just before death.

3. To increase the circulating blood volume and decrease the disproportion between the diminished blood volume and the size of the vascular bed:

Contraction of the spleen which is a huge reservoir for red blood cells produces an erythremia. Webster showed the restorative possibilities of the spleen by means of its hidden resources of blood cells which he excluded by preliminary removal of that organ. Some evidence of the source of part of the restorative fluid was discovered by excluding certain viscera from the circulation. In their absence the rate of blood dilution was greatly diminished. There are observations to support the belief that even in man the immediate rate of entrance of fluid into the

blood stream after hemorrhage may amount, for a time, to 0.25 c.c. per kilogram of body weight in a minute.

Reduction in capacity of the vascular bed occurs and there results a redistribution of the blood. This is accomplished by vasoconstriction which is known as the "physiological tourniquet." By this method blood is withdrawn from the less important parts and organs and is given to the more vital ones. The pallor of the skin and mucous membranes and the coldness of the body is a part of the phenomenon of shock, in this instance due to loss of blood. It is a conservative dynamic mechanism designed to prevent irreversible shock in which instance there is peripheral vascular failure. The skin, then, becomes mottled and cyanotic in places. Pressure causes a blanching of the skin which returns to its previous color very slowly.

Adolph has summarized the further *immediate effects* of hemorrhage as follows: the primary effect of loss of blood from the circulation is to *decrease the rate of blood flow and oxygen flow to most tissues.* To this situation the circulation responds by increase in heart rate, discharge of epinephrine, discharge of blood from the spleen, local vasoconstrictions, and local persisting ischemias. The respiration responds to the local asphyxia in its centers and to the pouring of lactate into the circulation by hyperventilation (dyspnea and "air hunger"), followed eventually by anoxemia and cessation of breathing.

Hemodilution attempts to restore blood volume. This begins immediately after hemorrhage and is due to the lowered hydrostatic and unchanged osmotic pressure of the blood which causes water to be drawn in from the tissue spaces (Chapter 11). In the capillaries, fluid flows into the blood from the tissue spaces, water excretion by the kidneys is diminished, and various dissolved constituents interchange in response to the lowered pressures, to the anoxemia, and to the altered types of tissue metabolism. After several hours the blood becomes diluted and therefore the red cell concentration is reduced. This constitutes the most reliable means of differentiating hemorrhage from shock; in shock, plasma is lost so that the red cell concentration is increased. This hemoconcentration in shock begins within one-half hour; in hemorrhage, dilution may be detected within two hours, although it is sometimes greatly delayed, especially in dehydration. Later, after the blood volume has been restored, protein is added to the blood by way of the lymphatics, which are found to contain more protein, for there is a greater concentration of protein in the intercellular fluid. This is due to increased capillary permeability from anoxemia. Intercellular fluid enters by absorption through the blood capillaries. The extreme thirst of the patient after hemorrhage is easily understood, for the tissue cells have been depleted of their fluid content.

If the capillaries have been injured, as in crushing wounds, or if the hemorrhage is great and prolonged, or if there is dehydration, capillaries

become permeable to colloids (in the former case due to direct injury and in the latter due to anoxemia). This permits loss of plasma and results in a high hematocrit reading. Some fluid is attracted into the blood stream and is promptly lost again with more plasma, thereby producing hematogenic shock (see Chapter 14). In dehydration there is very little intercellular fluid to draw upon and therefore shock which is irreversible may soon occur. Thus hemoconcentration may be present and persist in hemorrhage. Usually there is a normal hematocrit early, then a low one. The observation that shock due to trauma begins with hemoconcentration whereas shock due to hemorrhage ends with hemoconcentration is ordinarily, although not invariably, correct. The reasons for this phenomenon have usually been explained by the increased permeability of the capillaries. In shock they leak early due to trauma; in hemorrhage late due to anemic anoxemia. Fluid is also lost in both instances by rapid respiration and leaky skin. Recent experiments tend to disprove the hypothesis of leaky capillaries as a cause of irreversible shock in hemorrhage—rather it is due to permanent injury of tissue cells from anoxemia and dehydration. Probably both factors are responsible. However, it is important to remember that transfusions are often restorative in shock due to hemorrhage, even after many hours. This is not true in traumatic shock. Ultimately, though, shock due to hemorrhage is also irreversible.

Replacement of the red and white cells and protein.—This is done by the blood-forming organs and takes several days or weeks. The liver is usually not damaged in hemorrhage. Bone marrow is stimulated by the anoxemia in hemorrhage. The reason for this is that the most important factor in erythropoiesis is the oxygen tension in bone marrow. Conversely blood transfusion depresses it as does the inhalation of oxygen.

CAUSES OF BLOOD LOSS AND KINDS OF BLEEDING

Bleeding may occur from the arteries, the veins, or the capillaries. It may be internal, external, or concealed and may be primary or secondary. Arterial bleeding may be identified by the bright red color, the force, and the spurting tendency. A lateral tear in an artery bleeds more than a transverse one due to separation of the wound by contraction of the circular muscle in the media. Venous bleeding is darker, and although it may have considerable force, it does not approach that of arterial and does not spurt. Capillary bleeding is an ooze and its color depends upon whether there is a predominance of venules or arterioles in the wound. While it is true that in most cases of hemorrhage due to accidents both veins and arteries are involved, yet it is necesssary to distinguish between them, especially if one or the other is injured alone.

When hemorrhage occurs from certain organs, special names are applied: *epistaxis* refers to bleeding from the nose; *hematemesis*, to bleeding from the stomach; *hemoptysis*, to bleeding from the lungs; *menor-*

rhagia, to profuse or abnormal bleeding from the uterus at menstrual time; and *metrorrhagia*, to bleeding between periods. It is probably well to drop these terms and speak of gastric hemorrhage, pulmonary hemorrhage, etc.

External hemorrhage and internal hemorrhage are what the names imply. The former occurs on the outside and can easily be seen. The latter occurs within the abdomen or thorax, or within one of the parenchymatous organs such as the liver, spleen, or one of the kidneys. Concealed hemorrhage is a term used to indicate bleeding into muscle or beneath the skin. This is very important in accidents and usually causes a profound state of shock (Chapter 14).

Immediate hemorrhage means one that occurs at the time of operation. Delayed or secondary hemorrhage usually refers to bleeding which occurs after forty-eight hours as a result of a slipped ligature or infection about a vessel which causes the clot to become loose.

SYMPTOMS AND SIGNS OF HEMORRHAGE AND THE DETERMINATION OF THE AMOUNT OF BLOOD LOST

The symptoms accompanying hemorrhage may be said to depend on the amount and rapidity of the bleeding. Small hemorrhages produce few or no immediate symptoms, unless because of the psychic effect simple fainting occurs. Large hemorrhages produce symptoms of shock. If the hemorrhage is small in amount and continued over a long period, a profound state of anemia occurs. A sudden large hemorrhage produces shock, but the patient may quickly rally, especially if the bleeding is controlled. However, if a large volume of plasma has been lost, symptoms may persist in an alarming way even after the arrest of the hemorrhage. *In both instances there is a loss of blood volume followed by cardiac inadequacy and a fall in blood pressure.* The patient appears pale, the lips are blanched, and the skin is moist and cold. *He is extremely restless.* The temperature is below normal, the pulse is rapid and thready, and the respiration is rapid and shallow, or sighing. The patient complains of being unable "to get his breath" and of weakness and thirst. The restlessness is a compensatory mechanism to increase venous return through muscular contraction. Patients after a severe hemorrhage desire to be propped up in bed, or to lean forward, hoping to alleviate the dyspnea. These symptoms may ameliorate when the "compensatory mechanism" takes hold, only to revert back into more severe ones as the bleeding progresses. Hence the patient is said to have a succession of fainting spells.

In concealed hemorrhage, where bleeding is slow but continuous due to capillary damage, profound shock occurs (Chapter 14). Whereas the foregoing symptoms are those of the typical case, many variations occur. We have already noted that the pulse may be slow and the blood

become permeable to colloids (in the former case due to direct injury and in the latter due to anoxemia). This permits loss of plasma and results in a high hematocrit reading. Some fluid is attracted into the blood stream and is promptly lost again with more plasma, thereby producing hematogenic shock (see Chapter 14). In dehydration there is very little intercellular fluid to draw upon and therefore shock which is irreversible may soon occur. Thus hemoconcentration may be present and persist in hemorrhage. Usually there is a normal hematocrit early, then a low one. The observation that shock due to trauma begins with hemoconcentration whereas shock due to hemorrhage ends with hemoconcentration is ordinarily, although not invariably, correct. The reasons for this phenomenon have usually been explained by the increased permeability of the capillaries. In shock they leak early due to trauma; in hemorrhage late due to anemic anoxemia. Fluid is also lost in both instances by rapid respiration and leaky skin. Recent experiments tend to disprove the hypothesis of leaky capillaries as a cause of irreversible shock in hemorrhage—rather it is due to permanent injury of tissue cells from anoxemia and dehydration. Probably both factors are responsible. However, it is important to remember that transfusions are often restorative in shock due to hemorrhage, even after many hours. This is not true in traumatic shock. Ultimately, though, shock due to hemorrhage is also irreversible.

Replacement of the red and white cells and protein.—This is done by the blood-forming organs and takes several days or weeks. The liver is usually not damaged in hemorrhage. Bone marrow is stimulated by the anoxemia in hemorrhage. The reason for this is that the most important factor in erythropoiesis is the oxygen tension in bone marrow. Conversely blood transfusion depresses it as does the inhalation of oxygen.

CAUSES OF BLOOD LOSS AND KINDS OF BLEEDING

Bleeding may occur from the arteries, the veins, or the capillaries. It may be internal, external, or concealed and may be primary or secondary. Arterial bleeding may be identified by the bright red color, the force, and the spurting tendency. A lateral tear in an artery bleeds more than a transverse one due to separation of the wound by contraction of the circular muscle in the media. Venous bleeding is darker, and although it may have considerable force, it does not approach that of arterial and does not spurt. Capillary bleeding is an ooze and its color depends upon whether there is a predominance of venules or arterioles in the wound. While it is true that in most cases of hemorrhage due to accidents both veins and arteries are involved, yet it is necesssary to distinguish between them, especially if one or the other is injured alone.

When hemorrhage occurs from certain organs, special names are applied: *epistaxis* refers to bleeding from the nose; *hematemesis*, to bleeding from the stomach; *hemoptysis*, to bleeding from the lungs; *menor-*

Should bleeding persist, operation is indicated, especially in older patients, who stand the loss of blood poorly. Of course, it would be better to wait until the patient had recovered from the hemorrhage—many patients are lost by overconservatism. Younger ulcer victims will usually recover from the first hemorrhage but even here a recurrence demands surgery. (See Chapter 20.)

Bullet wounds of the abdomen or severe trauma are followed by recovery almost in proportion to the amount of bleeding encountered and the time interval before intervention. There is only one way to control prodigious internal bleeding from trauma and that is by open operation with ligation or suture of the bleeding part. If this ligation impairs the blood supply of an organ, the organ must be removed. Since patients with large hemorrhages are usually in shock, this is combated by adequate replacement of blood immediately before and during the operation. Two large veins, preferably in the ankle, are cannulized and blood plasma and saline are infused. If upon opening the abdomen massive hemorrhage is encountered, blood may be given almost as fast as it is lost. Another devise may be added for safety. Should the blood pressure fall to such levels that cardiac inadequacy prevails precluding the rapid ingress of blood, the vital fluid may be forced into the veins by an attached 50 c.c. syringe with a three-way stopcock. In intra-abdominal bleeding the course of the bullet is traced. What organs were in its path? What vessels are likely to be torn? Incision is made which is adequate. These vessels are seized and tied; if a solid organ is torn, the rent is packed with gauze until the extent is estimated and sutures can be introduced. In combined thoracic and abdominal wounds the same procedure is followed. A typical example of this problem may be cited.

A young soldier who had just returned from Germany was dismantling a 38-caliber revolver. He shot himself in the fifth interspace just to the right of the sternum and the bullet emerged below the twelfth rib in the loin. He was in profound shock. The right chest was dull, the abdomen tense, and the urine bloody. His blood was typed and 3,000 c.c. of plasma were given, which was followed during surgery with 1,500 c.c. of whole blood. Incision was made in the ninth intercostal space posterolaterally. The internal mammary artery was tied at both ends. Two large holes in the upper and lower lobes of the lung were sutured. The diaphragm was opened and the liver found to be badly torn. It was packed temporarily and the retroperitoneal space opened. The right renal vein had been severed and the kidney badly torn. Right nephrectomy was done and the liver was sutured. The patient made a quick recovery. This story probably was duplicated in World War II thousands of times.

Ligation.—The ideal way to arrest bleeding from a vessel is by ligation. Some have advocated the simultaneous ligation of artery and vein where large vessels to an extremity are involved in order to prevent gangrene. Ligation of the concomitant vein is said to increase the venous pressure and thereby cause a dilatation of the venules which in turn is transmitted into the arterioles; thus there develops a more ample collateral circulation than might otherwise have occurred. Experimental and clinical studies have not substantiated this claim.

pressure normal. These are transient episodes as a rule and are not seen in severe cases after a variable interval. *It is this interval which is apt to deceive the surgeon during and after surgery.* Blood loss cannot be determined early by clinical symptoms or signs or by the hematocrit, hemoglobin, or plasma protein determinations. After the patient reaches a point where compensatory mechanisms no longer prevail, sudden and dramatic shock may occur. This often happens near the end of the operation or soon after the patient is returned to his room. Shock may not occur at all, *yet a blood loss of 500 to 750 c.c. may retard recovery. It* is, therefore, desirable to know the amount of blood lost during an operation, so that it may be replaced. Blood loss has been ascertained by washing sponges, drapes, and gloves, measuring the quantity in the aspirating bottle, and then testing the hemoglobin. Since the preoperative hemoglobin is known, then the $\frac{\text{Hgb lost}}{\text{Hgb preoperative}} \times 100 = $ c.c. blood lost.

Another method is to use dry sponges of known weight and weigh them as they are discarded. In this way blood may be given as it is being lost. Our method is based upon an estimation of the amount of blood usually lost in the particular kind of procedure and then commensurate replacement as the operation progresses. Should there be an unusual amount of bleeding, the amount is increased. The amount of blood lost *may be small, but in children or light patients it may mean a large per* cent of body weight and must be replaced. Our method is admittedly inaccurate but will prevent sudden collapse during the symptomless periods of hemorrhage.

METHODS OF CONTROL OF HEMORRHAGE

Natural Arrest.—Nature may stop a hemorrhage without surgical aid and frequently does so. This is accomplished by clotting, *retraction* and contraction of the vessel wall, and lowered blood pressure, which not only favors clotting, but allows the clot to begin its organization. Anything which interferes with the organization of the clot prolongs bleeding. Without clot formation and organization, hemorrhage is not arrested, even though the vessel be ligatured or sutured. Scalp vessels are held in the tight subcutaneous layer and cannot retract and contract well; *therefore bleeding from scalp wounds is profuse.* An example of the management of hemorrhage is the treatment of bleeding from a gastric ulcer. This consists of rest to the part (a limited amount of water, bland food, small doses of alkalis to neutralize the irritant action of the hydrochloric acid), absolute rest for the patient (through ample doses of morphine), and small and repeated *blood transfusions (not enough* greatly to increase the hydrostatic pressure, yet enough definitely to *increase* the osmotic pull). The introduction of large quantities of fluid intravenously may raise the blood pressure and lower the osmotic pull sufficiently to release clots and cause more hemorrhage.

Should bleeding persist, operation is indicated, especially in older patients, who stand the loss of blood poorly. Of course, it would be better to wait until the patient had recovered from the hemorrhage—many patients are lost by overconservatism. Younger ulcer victims will usually recover from the first hemorrhage but even here a recurrence demands surgery. (See Chapter 20.)

Bullet wounds of the abdomen or severe trauma are followed by recovery almost in proportion to the amount of bleeding encountered and the time interval before intervention. There is only one way to control prodigious internal bleeding from trauma and that is by open operation with ligation or suture of the bleeding part. If this ligation impairs the blood supply of an organ, the organ must be removed. Since patients with large hemorrhages are usually in shock, this is combated by adequate replacement of blood immediately before and during the operation. Two large veins, preferably in the ankle, are cannulized and blood plasma and saline are infused. If upon opening the abdomen massive hemorrhage is encountered, blood may be given almost as fast as it is lost. Another devise may be added for safety. Should the blood pressure fall to such levels that cardiac inadequacy prevails precluding the rapid ingress of blood, the vital fluid may be forced into the veins by an attached 50 c.c. syringe with a three-way stopcock. In intra-abdominal bleeding the course of the bullet is traced. What organs were in its path? What vessels are likely to be torn? Incision is made which is adequate. These vessels are seized and tied; if a solid organ is torn, the rent is packed with gauze until the extent is estimated and sutures can be introduced. In combined thoracic and abdominal wounds the same procedure is followed. A typical example of this problem may be cited.

A young soldier who had just returned from Germany was dismantling a 38-caliber revolver. He shot himself in the fifth interspace just to the right of the sternum and the bullet emerged below the twelfth rib in the loin. He was in profound shock. The right chest was dull, the abdomen tense, and the urine bloody. His blood was typed and 3,000 c.c. of plasma were given, which was followed during surgery with 1,500 c.c. of whole blood. Incision was made in the ninth intercostal space posterolaterally. The internal mammary artery was tied at both ends. Two large holes in the upper and lower lobes of the lung were sutured. The diaphragm was opened and the liver found to be badly torn. It was packed temporarily and the retroperitoneal space opened. The right renal vein had been severed and the kidney badly torn. Right nephrectomy was done and the liver was sutured. The patient made a quick recovery. This story probably was duplicated in World War II thousands of times.

Ligation.—The ideal way to arrest bleeding from a vessel is by ligation. Some have advocated the simultaneous ligation of artery and vein where large vessels to an extremity are involved in order to prevent gangrene. Ligation of the concomitant vein is said to increase the venous pressure and thereby cause a dilatation of the venules which in turn is transmitted into the arterioles; thus there develops a more ample collateral circulation than might otherwise have occurred. Experimental and clinical studies have not substantiated this claim.

Concussion of an artery leads to spasm with absent pulsation which may be misleading. When a ligature is applied, intima should be in contact with intima. This contact should be broader in large vessels (that is, the ligature should be larger) and narrower in smaller vessels. The trauma to the intima stimulates clotting. (The ligature should not be so tight as to cut through the vessels.) The circular muscle fibers in the media contract, constricting the lumen further. Soon fibroblasts, fibrocytes, macrophages, and leucocytes appear on the fibrin within the clot. (The fibroblasts come from the adventitia.) Collagen forms and hardens, debris is removed by the macrophages, and the endothelium proliferates to cover the site of the ligature, making the vessel smooth. It is well to transfix the ligature and leave a cuff of about one-eighth inch so that it will not be forced off the end of the vessel.

Heavy silk or cotton is preferable to catgut for ligature because it is more pliable and has a greater coefficient of resistance so that knots do not slip. For largest vessels umbilical tape has been advocated by some.

A partial division of a vessel or a lateral tear may bleed more profusely than a complete transection, due to contraction of the circular muscle in the tunica media, which further opens the wound. Frequently a "false aneurysm," or large hematoma, may form. In such cases ligation proximally and distally must be done and the sac obliterated. Indeed, both sides of a divided artery must always be tied, for bleeding will occur both proximally and distally to the wound, due to collateral circulation. This is especially true in the larger arteries and such smaller vessels as the internal mammary and deep epigastric. Ligation and division of large arteries is preferable to ligation in continuity because in the latter there may be erosion and hemorrhage or reestablishment of lumen; also, years later such a procedure may be followed by pain, poor pulse, and claudication. Should this occur even division of so little as a fibrous cord relieves pain. When the artery is divided, the retracted, thickened, and expansile end obviates the above. Badly mangled vessels bleed very little because the trauma injures the intima and the injury stimulates clotting. Thrombi form which cause the arrest of hemorrhage in the smaller vessels and often, temporarily, in the large ones. Thrombosed arteries do not lend themselves to primary suture. These thrombi may give rise to emboli. If badly contused, ligation above and below and excision of the thrombosed area should be done. Suturing is disappointing because of thrombosis. Even if successful, aneurysmal dilatation may follow or there may be severe pain and disuse of the extremity with atrophy. In some instances, if the wound is an incised one (and is lateral or involving part of the circumference) and if the patient is seen within six hours so that complete sterilization can be effected, suture of the vessels may be attempted. It is best to use fine, waxed silk for this, and intima should be approximated to intima if possible. How-

ever, until the ligature can be used, temporary means of stopping the hemorrhage must be employed. Perhaps the best is the tourniquet. Anything may be used—a handkerchief may be twisted or a catheter may be tied tightly. Although experiments to the contrary have been reported, we have found a wide rubber bandage such as the Esmarch band *or blood pressure cuff is best.*

Temporary Control by Tourniquets.—By consulting the diagrams an idea may be obtained as to the more advantageous sites for applying tourniquets. It should be noted that the tourniquet is applied where the vessel is in immediate contact with bone and can be compressed against it. In the arm this would be above the elbow, and in the leg, above the knee, compressing the brachial artery and the femoral artery, respectively.

Although this point of compression stops the hemorrhage most effectively, yet it should be borne in mind that the radial nerve in the arm and the sciatic nerve in the leg demand a broad elastic tourniquet to *avoid injury to these structures if the tourniquet must remain in position* for a considerable length of time. The elbow joint and knee joint areas should never be used for tourniquets because of the danger of injuring vesicles and nerves, particularly the common peroneal. The forearm and lower leg may have any type of tourniquet.

The tourniquet may be left in place up to four hours if it is of the broad elastic type. The five factors which limit the period of safety are *gangrene, injury to the nerves, trauma to the skin, decrease in tissue* resistance by anoxia, and shock on removal of the tourniquet.

Experimental and clinical evidence show that a tourniquet may be left on longer when the extremity is packed in ice. This procedure is unnecessary as a rule and may lead to gangrene as a result of the cold. (See Chapter 6.) The tourniquet may be released temporarily to facilitate reoxygenation. During this time bleeding may be controlled by digital pressure and elevation of the extremity. If this is impossible the tourniquet must be left in place. We shall discuss the effect on the blood pressure after release of the tourniquet in Chapter 14. It is pertinent to recall that all preparation should be made for attention to the wound when the tourniquet is released and blood transfusion should be in progress. This may prevent a severe state of shock. It is better to apply an elastic pressure bandage with control of bleeding than to use the tourniquet to control bleeding. In every instance the extremity should be elevated for a few minutes before applying the pressure bandage. These measures are designed to prevent the sudden pooling of blood into the injured extremity following the release of the tourniquet, whether this pooling is due to paralysis of vessel walls or vasodilation. Local axonal nerve reflexes with dilatation of the capillaries, or dilatation due to local tissue histamine-like substances or due to an increased acidity of tissues, all play a role in the production of so-called tourniquet shock.

From this discussion it is obvious that in contemplating surgery, tourniquets are not often employed. In such cases the blood supply is controlled first by ligatures. It is in traumatic surgery, as well as in vascular surgery, that tourniquets are employed, and here the limitations in such procedures should be fully understood. (See Chapter 17).

Needless to say, the tourniquet must be applied between the heart and the site of hemorrhage. In the neck, pressure is applied on the carotid artery by compressing it against the carotid tubercle. It has been said that a broad band used as a tourniquet will cause more damage to the vessel than a narrow one, because of a wider area of compression

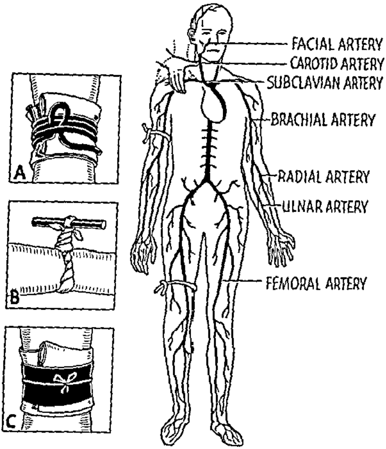

Fig. 106.—Diagram illustrating types of tourniquet and places of application. *A.* Soft rubber tube wrapped around a towel. *B.* Handkerchief tied around a stick and twisted. *C.* Esmarch bandage—the ideal type of tourniquet for the control of hemorrhage.

The large figure indicates the proper sites for the application of the tourniquet. It should be above the elbow and knee where the main vessels can be compressed against the underlying bone. The hand indicates the sites of pressure in the event of bleeding from the common carotid, which has no branches, except its terminals (the external and internal carotids). Pressure is applied medially against the cervical spine. The dotted hand indicates the direction of pressure in hemorrhage from the subclavian artery. Obviously, pressure is made proximal to the wound in the vessel—that is, between the injury and the heart. Venous bleeding may be controlled by pressure at the site of hemorrhage.

injury. This may be true, but our experience has been that narrow bands left on for two hours or more are more apt to produce a paralysis due to nerve injury or gangrene due to arterial and venous damage. It is true that if an extremity is packed in ice and the temperature m

at about 5° C. a tourniquet may remain for seven to ten hours without resultant gangrene. This is useful where transportation over a long distance is necessary. Usually, however, gangrene supervenes after such treatment and amputation is necessary.

Pressure for the Control of Hemorrhage.—Venous bleeding is best stopped by using pressure at the site of hemorrhage. The vein has thin walls which are readily compressed, and it is unnecessary to use a tourniquet. To be effective, a tourniquet must be tight enough to occlude the arterial flow: Should the pressure applied by tourniquet be less than systolic, it would only increase the venous bleeding. Tourniquets applied below the site of hemorrhage in venous bleeding also tend to increase it, due to collateral communication.

It may be said that pressure at the site of bleeding may be used in any type of hemorrhage, and, if firm enough, will be effective. In the case of a large bleeder, the finger may be used until a tourniquet can be applied. Every surgeon has encountered severe bleeding during an operation. Until he can apply a hemostat he will invariably control the flow of blood with the fingers. Capillary oozing is best arrested by pressure. This is applied usually by gauze packing and is especially useful in bleeding from the nose, from a tooth socket, from the cervix, or from the uterus. Packing should be left in long enough for clotting to occur and, if possible, for a sufficient exudate to form to loosen the packing. This may be twenty-four to forty-eight hours, or even longer. If simple pressure is applied to capillary ooze on the surface, one must remember that at least four to six minutes are necessary to effect clotting. In the case of a mangled extremity, the bleeding is usually concealed, and a tight elastic bandage over a previously applied sterile bandage controls capillary as well as arterial bleeding most effectively and with the least amount of shock after its release.

Local Coagulants and Hemostatics.—Styptics, such as 10 per cent silver nitrate or glacial acetic acid, are sometimes used in the nose or throat effectively. The escharotic action of these solutions predisposes the area to recurrent bleeding. A piece of skeletal muscle held with pressure is often effective. Fibrin foam prepared from human fibrinogen and thrombin is now available in sterile tubes. The film is soaked in physiological saline and then removed and kept in cool saline. It has been left in place as a dural substitute and has also been used over raw surfaces in the abdomen. Topical thrombin is excellent, producing coagulation in a few minutes. The gelatin sponge may be left in place producing hemostasis and ultimately being absorbed with fibrous tissue replacement. Oxidized cellulose or cellulosic acid (absorbable gauze) is also effective but is absorbed more slowly and causes more adhesions to form. It cannot be used with topical thrombin because its acid reaction inactivates thrombin, whereas if alkaline solutions are used, the gauze is ineffective.

Agents Used to Increase Coagulability of the Blood.—Human plasma is perhaps the most effective substance to increase blood coagulability. Whole blood should also be used because the agglutination of platelets and erythrocytes is the starting point of thrombus formation; therefore they must be present in ample quantity. Since abnormal bleeding tendencies have already been discussed, we need only recall that the following deficiencies may be present: thromboplastin, for which whole blood and plasma is necesssary; prothrombin, for which vitamin K is essential; fibrinogen, which is most effectively treated by plasma and blood transfusions; calcium may be used because of its indirect action on the liver; erythroblastosis is perhaps best treated with Rh-negative blood.

Dozens of commercial products are available which are supposed to accelerate blood coagulation. Most of them are inert. Oxalic acid is apparently an effective hemostatic agent. Under the heading of anticoagulants we have stated that sodium, potassium, or magnesium oxalate will prevent clotting in vitro. Calcium oxalate is formed, causing calcium depletion and prolonged clotting time even in vivo and if given in excessive amounts will cause death of the animal. However, when given in small amounts, coagulation time is reduced even in hirudinized animals, indicating that here it is antagonistic to antithrombin. The normal person has about 5.5 to 7.5 mg. of oxalic acid per 100 c.c. of blood. Oxalemia accompanies hyperglycemia and perhaps this is the reason for reduced coagulation time produced by the administration of glucose or adrenalin. Oxalic acid given intramuscularly in 20 mg. doses may help in the control of capillary bleeding due to prolonged coagulation time.

I have on two occasions operated upon physicians, who had hemophilia. In one, who was a resident in medicine, the coagulation time was thirty-two minutes. He had an acute appendicitis which at operation was found to be gangrenous. The second was an intern with a strangulated inguinal hernia. His clotting time was twenty-nine minutes. In both, 1,000 c.c. of plasma were given before and during surgery. Meticulous hemostasis was observed. Both recovered without any bleeding episodes. In both cases procrastination was untenable. Both knew that they had hemophilia. These cases are cited to prove that perhaps the major portion of postoperative bleeding is due to inadequate attention to the smaller vessels which should be tied.

REPLACEMENT OF BLOOD

After the temporary arrest of the hemorrhage treatment is directed to the patient as a whole, for he will usually be in a state of shock and operations should not be done with a patient in shock even though they are apparently minor. A good rule to follow is: arrest hemorrhage first and then treat the patient for shock. After reaction has occurred, attention should be given to the wounds.

Experiments have shown that an amputation may be done successfully *with hemoglobin values as low as 28 per cent.* Surgeons regard a hemoglobin value of 50 per cent as the lower limit of safety as a rule. The limit varies, of course, with the general condition of the patient.

This means that a patient in shock will not tolerate the loss of blood even though it be trivial. Furthermore, we have seen that hemoglobin and erythrocyte values may be normal for several hours after a severe hemorrhage, thus misleading the surgeon.

Obviously the first consideration will be the replacement of blood. For this, fresh whole blood is best. Patients with continued blood loss and continual replacement are bad risks even though blood counts and hemoglobin are within normal limits. This is due to the severe crippling changes which occur in tissue cells as a result of continual anemic anoxemia. Surgical wounds heal poorly and renal or hepatic insufficiency is apt to occur. These observations are often seen in bleeding peptic ulcer. Here surgery should be done early for persistent hemorrhage (forty-eight hours), and if not we should wait for spontaneous arrest. Should surgery become mandatory, the simplest procedure possible is done.

Whole Blood

A fundamental rule in restoring blood volume is to replace that which which has been lost. In hemorrhage it is whole blood. Later we shall discuss substitutes, but first we should enumerate the reasons for giving whole blood, then outline the differences between fresh and stored blood, and finally list the reactions from blood transfusions.

Whole blood may be given in any condition in which there has been a decrease in circulating blood volume from any cause, including the loss of plasma and electrolytes in burns. The transport of oxygen by the red cells, the maintenance of osmotic pressure by the plasma proteins, the coagulation of blood through the prothrombin-fibrinogen mechanism, nutrition as supplied by plasma proteins, participation in immunity reactions through complement and circulating antibodies, and phagocytosis by the leucocytes are all functions of whole blood, making it the fluid best suited to fortify the circulation. Patients tolerate a slow loss of blood well, but when red cells are suddenly removed in large numbers, an anemic anoxemia results which can only be met by introducing red cells (even the inhalation of 100 per cent oxygen will not help if there are not enough cells to carry it). Pure crystalline human hemoglobin may be made from discarded red cells in blood banks. This is still in the experimental stage.

Giving fresh blood means careful typing and compatibility tests, Rh factor determination, especially in women, and the availability of compatible donors. While this is ideal it is as a rule impractical and therefore most hospitals have blood banks from which compatible stored blood may be had at all times. Blood transfusions are almost uniformly

given by the indirect citrate method. This is simple and efficient. Blood is drawn from the donor in a vacuum bottle in which there is a solution of sodium citrate. It is typed and used or stored. Stored blood is kept at 2 to 4° C. for ten days but no longer because hemolysis takes place in increasing amounts. After ten days the plasma is removed and may be used (care being taken to leave the buffy coat and hemolyzed cell layer because these cause reactions). This plasma may then be dried, frozen, or kept in a liquid state in refrigeration. Stored blood has other disadvantages:

1. By using radioactive iron, donor red blood cells can be labeled. The storage of citrated blood exerts a deleterious effect on the survival of transfused erythrocytes. Their survival varies inversely with the duration of storage. The iron of destroyed transfused erythrocytes is utilized for the synthesis of hemoglobin.

2. The potassium content of whole blood is greatly increased even without hemolysis; at the end of one week it may reach five to ten times the normal amount. Hyperpotassemia may cause convulsions or cardiac effects.

3. Prothrombin content is depressed up to 25 per cent by the end of seven days.

4. Electrophoretic patterns indicate certain alterations in proteins, but their significance is not definitely known.

5. The antibody effect is less, even though the globulin content is normal.

6. Leucocytes are decreased 50 per cent after five days of storage. Moreover, the remaining white corpuscles lose some of their phagocytic powers.

7. Platelets survive only two to five days.

We have stated that the indirect method is by far the more practical; however, the dangers of excessive amounts of citrated blood given within a very short period should be mentioned. Severe toxic reactions may occur from the sodium citrate. This may be due to its effect on heart muscle or its ability to shorten clotting time due to destruction of platelets, with resulting thrombi; it may form a complex salt with calcium and remove it—this, as we have seen, prevents clotting in vitro and may produce tetany in vivo.

As little as 0.11 to 0.15 Gm. of sodium citrate per kilogram of body weight may be lethal when given in plasma or blood. Therefore 2,500 to 3,500 c.c. of blood or plasma given rapidly to a person weighing 70 kilograms may be toxic (since 10 c.c. or a 2.5 per cent solution of sodium citrate is used for every 100 c.c. of blood), although we have never recognized this phenomenon in our patients thus far.

Reactions from blood transfusions may also occur due to pyrogenic substances in glassware or tubing, imperfect technique, too rapid injection, or too much blood, especially in children. In the latter there may

result an embarrassment to the right side of the heart. The quantity is about 20 to 30 c.c. per kilogram of body weight or 10 to 15 c.c. per pound or about 25 to 30 per cent of the total blood volume; however, this varies with the amount lost which should be adequately replaced. In adults *larger amounts may be given up to 45 c.c. per kilogram or 50 per cent* total blood volume. It is usually better to replace blood slowly after control of hemorrhage because diluting mechanisms may have already replaced part of blood volume temporarily. Incompatibilities may cause severe, even fatal reactions. Symptoms include precordial pain, which may be referred "straight through" to the back, tingling pains all over the body, cyanosis, and all signs of shock. Hemoglobin appears in the urine. Symptoms are due to the mechanical effect of agglutinated corpuscles, causing a blockage of vessels to vital organs. Hemolysis of agglutinated cells occurs late. The tubules of the kidneys are blocked with hematin produced by the action of the acid urine on the liberated hemoglobin. This may cause anuria. Reactions may also occur due to the ingestion of protein or other food by the donor—these may resemble anaphylaxis or serum sickness. Intragroup reactions may be due to the Rh factor or isoimmunization with the A and possibly B antigen in mothers.

Treatment of Transfusion Reactions.—For any type of reaction the *transfusion should be stopped at once. In the less severe, a change of* tubing may be all that is necessary. In the severe types due to incompatibility, active treatment is required in addition to stopping of the transfusion. This consists of giving plasma if necessary as a substitute, giving large doses of sodium bicarbonate by mouth if possible (if not, intravenously) to alkalinize the urine; also a 1/6 molar sodium lactate solution may be used intravenously if the patient cannot swallow. Beware of overhydration in anuria due to transfusion reaction; however, extra sodium which is needed in hemoconcentration and acidosis must be supplied with physiological saline solution. Osmotic pressures may be sustained with plasma.

Substitutes for Whole Blood

Plasma.—When blood stands, plasma and serum form on top. Serum contains no fibrinogen. Plasma is preferable to serum because the latter contains substances which exert vasomotor effects and there are other unfavorable reactions. Plasma may be preserved in liquid, frozen, or dried state. In civilian use liquid or frozen plasma is best, although the former offers the least resistance to bacterial growth. Dried plasma losses prothrombin when diluted with sterile, distilled water. If 0.1 per cent citric acid solution is used, excessive alkalinity may be avoided and much prothrombin saved. Hypertonic solutions of the dried plasma should not be used; unlike iso-osmotic solutions they depend on the

intercellular fluid for their dilution. Since dehydration is apt to be present and since tissue water is being used to keep up blood volume, iso-osmotic plasma is best.

Albumin solutions may be used and are available. They are best suited for the treatment of shock in military campaigns. Since the albumin fraction is the most important in maintaining osmotic pressures, this solution is useful, but if given in hypertonic solution it is objectionable for reasons given.

In general, plasma is useful to avert shock from hemorrhage. A patient already in shock stands the loss of blood poorly. Shock due to hemorrhage begins abruptly when compensatory mechanisms fail (q.v.). Here plasma restores blood volume, keeps up osmotic pressure, provides a normal medium for carrying all available red cells, and serves to mobilize sequestrated erythrocytes, actually increasing the number of circulating red corpuscles. Since the corpuscles increase in size after a hemorrhage, they are thought to be trapped in smaller vessels and are freed after plasma infusions restore normal osmotic and volume relations.

Red Blood Cells.—They may be given in physiological saline. This is impractical ordinarily. However, during World War II plasma was used and the cells discarded because in the earlier years of the conflict a satisfactory method for preserving whole blood for long periods had not been found. These cells were available in all blood donor centers and were used in treating hemorrhage. There were more reactions than with whole blood, and the cells could not be kept for more than seven to ten days.

Human Fluids.—Pleural fluid and ascitic fluid have been used and show promise of being useful if they can be given without serious reactions.

Other Proteins.—These have been discussed in the previous chapters. Amino acids and hydrolyzed protein are not useful as blood substitutes and may not be used even as a temporary measure in hemorrhagic shock. Gelatin has been tried but is apt to be followed by reactions.

Plant Derivatives.—Plant derivatives such as acacia and pectin while able to exert effective osmotic pressures are inert, interfere with oxygen absorption by the red cells, and impair the function of the liver and other parenchymatous organs. They also cause pseudoagglutination.

Crystalloids.—Physiological saline or isotonic (5 per cent) glucose solutions or combinations may save lives. Although their action is temporary for reasons already discussed (Chapters 11 and 12), they are able to bolster blood volume and supply the tissues with water and sodium. They are always available and are tolerated safely. Furthermore, they are useful to precede and follow transfusions of whole blood or plasma.

After reaction from hemorrhagic shock which is sufficient to permit definitive treatment, operations of necessity are performed. The pa-

tient is placed in an environmental temperature of about 72° F. and is carefully watched for secondary hemorrhage which may occur upon the return of a normal blood pressure. Pulse and blood pressure readings are made at one-half-hour intervals. Rectal temperatures are taken every three hours. A record is kept of fluid intake and output. In addition, hematocrit and plasma protein determinations (by copper sulfate method) are made every twenty-four hours to follow blood and plasma regeneration. Red blood counts and hemoglobin readings may be used as a supplement or in place of hematocrits if this method is not available. Thus the amount and type of fluid is given which is needed to restore normal values. As a rule very little is needed after the initial restoration of blood volume if the hemorrhage has been controlled.

Chapter 14
SHOCK

Shock is a term that is difficult to define because when used categorically it embraces such a vast array of disturbances that it is practically meaningless. Indeed an attempt to describe it leads to a recitation of so many variations in the clinical manifestations, causes, laboratory studies, and primary and secondary physiological effects that many have urged a discontinuance of the use of the term. Since the word is in common use it is well that we attempt to define it and then discuss the subject within the confines of the definition.

Shock is not a disease entity but a dynamic syndrome brought on by a general injury to the organism from nervous, mechanical, chemical, bacterial, or traumatic causes. Its symptoms are due to the failure of compensatory mechanisms to adjust to a sudden greatly diminished (rarely increased) *circulating* blood volume. Thus there are three principal reasons for shock: (1) a loss of blood volume so great that decreased adjustment of the vascular bed cannot occur; (2) an increase in volume so great that the vascular tree cannot increase enough; (3) a failure of adjustment due to (a) nervous or (b) organic change in the blood vessels. The symptoms of shock then are really the manifestations of the compensatory mechanisms in charge when the disproportion became too great for the maintenance of normalcy. Each symptom thus becomes an act of conservation designed to preserve the integrity of cells in such vital organs as the brain, heart and blood vessels, liver, kidneys, and lungs, for if such cells are irreparably damaged, then shock becomes irreversible and the individual will die even though restorative measures have been instituted.

Let us look at a patient who presents what has been termed the classical picture of shock and interpret these symptoms in the light of the foregoing concept.

The patient is pale, the lips are cyanotic, large beads of perspiration stand out on the forehead; he is oblivious to surroundings and lies motionless, with only occasional purposeless movements. If asked a question he will answer by "yes" or "no," but he will not volunteer any information. His respiration is shallow and, if shock continues, may become irregular; that is, of the Cheyne-Stokes type. Sometimes it is noisy (stertorous), or it has a sighing sound (sighing respiration). The temperature is subnormal—94 to 96° F. The patient is cold. The pulse is rapid and thready—140 to 150. The blood pressure is extremely low,

about 60 to 70 systolic. Sometimes there is an absence of diastolic pressure, but not often; if so, the prognosis is grave. The pupils are usually dilated.

There is a persistent low blood pressure due to a decreased circulating blood volume, although *rarely this may be due to a great and sudden* increase in blood volume. In either case there must be a prompt adjustment between the amount of blood and the vascular bed if tissues are to be properly nourished.

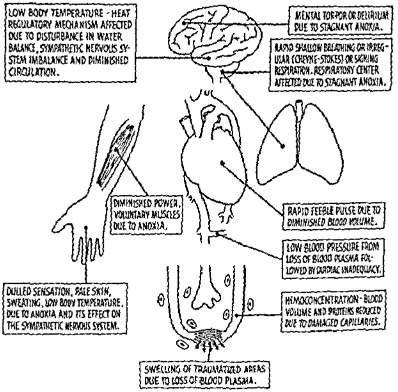

Fig. 107.—Diagram illustrating the clinical manifestations in shock and their probable causes.

Compensatory mechanisms come into play immediately. The carotid sinus reports a fall in pressure and there is vasoconstriction with cardio-acceleration—nature's way of raising blood pressure and increasing blood flow. The rapid thready pulse is evidence of an effort to race blood to the lungs which must breathe faster to provide sufficient oxygen. The stimulation of the respiratory center is due to anoxemia. As a result of peripheral vasoconstriction, the skin is pale and slightly cyanotic. This pallor varies in different kinds of shock. Thus in shock without blood loss pallor is accompanied by areas of cyanosis due to stagnation of blood in the venules; in hemorrhage which is severe there is very little cyanosis or there may be none because there is an insufficient amount of reduced hemoglobin; in infections the skin is plethoric. In any event the "peripheral tourniquet" is on to divert and hold blood in the vital centers. The skin is clammy and cold—evaporation through perspiration to

lower body temperature which in turn is necessary to slow the metabolism of cells so that they will not demand so much blood. So too, the lessened sensibility, mental dullness, and muscular relaxation are designed to conserve the need for blood; in short there exists a state of hibernation in which the body needs are reduced to a minimum so that vital centers may be kept alive with the diminished volume of blood.

The symptoms of shock reflect well-defined laws of physiology. We know that with vasoconstriction comes cardioacceleration, for this combination raises blood pressure. Conversely vasodilation and cardioinhibition is a combination which lowers blood pressure. Marey's law states that the pulse rate is inversely related to the arterial pressure and thus normally a rise in pressure causes a slowing of the heart rate. This is due to stimulation of the aortic plexus, afferent vagal nerves, or carotid sinus nerve. A fall in pressure is associated with an increase in heart rate.

The carotid sinus is a slight enlargement of the common carotid where it bifurcates into internal and external branches. Due to its rich nerve supply it is very sensitive to pressure changes. Chemical alterations in the blood affect the carotid body which may also produce changes in blood pressure and pulse rate so that mechanical or chemical alterations are detected and dealt with by these mechanisms. Compression of the carotid distal to the sinus, so as to raise the pressure in it, causes a slowing of the heart, vasodilatation, and a fall in blood pressure—this without the help of mechanically stimulating the vagus. Pressure proximal to the sinus, to produce a fall in pressure within the carotid, causes cardioacceleration, vasoconstriction, a rise in blood pressure, and liberation of adrenalin. The sinus has pressor and depressor effects. These are accomplished by the sinus reflex arc. The *afferent* component is by way of the sinus nerve a branch of the glossopharyngeal. Some fibers go to the carotid body (a sensory organ with functions like the sinus, sometimes the site of a tumor which must be excised). Centrally fibers make connections with the cardioinhibitory and vasomotor centers. The efferent fibers are composed of (a) a cardiac part by way of the vagus and (b) vasodilator and vasoconstrictors by way of the vagus and sympathetics.

A rise in the blood pressure of blood entering the right atrium causes an increase in heart rate—Bainbridge reflex. An inadequate amount of blood reaching the heart leads also to its increase in rate by way of the aortic and carotid sinus reflexes.

In shock normal physiological laws are operating but in various combinations. It is the summative effects of several factors—carotid sinus, aortic, visceral, somatic nerve stimuli; changes in blood volume, oxygen content, cardiac adequacy; and capillary permeability—all play a role in the excitation and integration of physiological processes which unite to conserve life and stop the vicious circle of shock.

Diagram of the Vicious Circle of Shock

A decrease in blood volume of less than 10 per cent produced by hemorrhage may elicit through constriction of central origin a decreased flow of blood through the submaxillary gland of more than 60 per cent even though accompanied by a rise in pressure. Indeed due to these mechanisms there may be an actual rise in blood pressure. Thus the diminished blood flow precedes the fall in blood pressure and this decrease in flow may be as much as 90 per cent before the pressure suddenly falls.

Anoxemia causes dilatation of capillaries with increased permeability and loss of plasma (Krogh). If oxygen is withdrawn for as long as three minutes, fluid escapes from capillaries at about four times the normal rate (Landis). Normal permeability can be restored within fifteen minutes by restoration of the normal blood supply which was diminished by the loss of plasma and water through the permeable capillaries.

This explains in part the difference between shock due to trauma in which increased capillary permeability is an initial derangement and shock due to hemorrhage in which capillaries begin to leak late due to anemic anoxemia. Shock will be delayed more in the latter, will be more amenable to treatment, and irreversibility will be postponed longer.

These are illustrations of the effects of injury on normal physiological processes and the great reserves present to protect and restore vital activities.

This clinico-pathologic picture of shock then is a synchronized dynamic mechanism invoked to sustain life—should it fail, irreversible shock ensues with peripheral vascular failure and blood is pooled in the skin. Although the causes are varied, the essential factor is a reduction in the circulating blood volume which results in disturbances of:

1. The central nervous system—caused by stagnant anoxia
   (a) Peripheral—dulled sensation
   (b) Central—mental torpor, or delirium
2. The sympathetic nervous system—caused probably by anoxia, sensory stimuli (in neurogenic shock), and reflex compensatory mechanisms
   (a) Pale skin, sweating, and low body temperature
3. The respiratory center—caused by stagnant anoxia
   (a) Rapid, shallow breathing
   (b) Irregular breathing (of the Cheyne-Stokes type); sighing or stertorous breathing
4. The circulatory system
   (a) Cardiac—caused by diminished blood volume
      (1) Rapid, feeble pulse

(b) Vasomotor—caused by primary factors (in neurogenic) or secondary factors (loss of blood volume), with arteriolar constriction and capillary dilatation
    (1) Low blood pressure
(c) Blood volume—due to damaged capillaries or loss of blood
    (1) Reduced (Mann found that normally 76 per cent of the total blood can be obtained from the large vessels of a dog at death. When death was due to shock, the large vessels yielded only 39 per cent of the total blood).

5. The heat regulatory mechanism—caused by disturbance in the water balance, sympathetic nervous system imbalance, and diminished circulation
    (a) Temperature usually low
6. The voluntary muscles—caused by stagnant anoxia
    (a) Diminished muscle power
7. The blood proteins—caused by loss of blood plasma through damaged *or dilated, and therefore more permeable, capillaries*
    (a) Low in amount

In general, we may speak of two forms of traumatic shock. The first is *primary* or *neurogenic* shock. This comes on immediately after injury and is presumably of reflex origin. It is characterized by an initial decrease in vasomotor tone with an early drop in blood pressure and a relative late decrease in cardiac output, the blood volume being unaffected. The second type is *secondary* or, as Burch and Harrison have called it, *hematogenic* shock. This comes on some time (an hour or two) after trauma and is characterized by: (1) a diminished blood volume, (2) an early fall in cardiac output, and (3) a relatively late fall in mean arterial pressure. *Collapse* has symptoms exactly like those of primary shock but is looked upon as having a functional rather than an organic cause and as being transitory in its action unless the disturbance is so severe that neurogenic shock results. However, Burch and Harrison use the term collapse synonymously with primary shock. It is perhaps common for primary and secondary shock to occur at the same time or follow each other. *Syncope* is synonymous with fainting. It is the mildest form of collapse.

HISTORICAL REVIEW

The term *shock* was first applied to this condition by James Latta in 1795. Travers in 1826 wrote on "An Inquiry Concerning Irritation" and called shock a "functional concussion." DeClasse in 1834, writing on "La Commotione," called shock an arrest of innervation. After Claude Bernard's discovery in 1852 of the sympathetic control of the blood vessels, Weir Mitchell, Moorehouse, and W. W. Keen in 1865 were the first to regard shock as a reflex motor paralysis. Loven in 1866 said that stimulation of the central end of a cerebrospinal nerve causes elevation instead of lowering of the blood pressure. Goltz's tapping experiments on frogs were written in a paper called "Klopfversuch" and caused Fisher in 1870 to reason that injury caused reflex paralysis of the vasomotor nerves, with a fall in blood pressure and a dilation of the great veins of the visceral region. Gross in 1872 poetically described shock as "a manifestation of a rude unhinging of the machinery of life."

Diagram of the Vicious Circle of Shock

Cardiac Inadequacy

Anoxemia

Diminished Circulating Blood Volume

Vasoconstriction or Vasodilation

A decrease in blood volume of less than 10 per cent produced by *hemorrhage may elicit through constriction of central origin a decreased* flow of blood through the submaxillary *gland of more than 60 per* cent even though accompanied by a rise in pressure. Indeed due to these mechanisms there may be an actual rise in blood pressure. Thus the diminished blood flow precedes the fall in blood pressure and this decrease in flow may be *as much as 90 per cent before the pressure suddenly falls.*

Anoxemia causes dilatation of capillaries with increased permeability and loss of plasma (Krogh). If oxygen is withdrawn for as long as three minutes, fluid escapes from capillaries at about four times the normal rate (Landis). Normal permeability can be restored within fifteen minutes by *restoration of the normal blood supply which was* diminished by the loss of plasma and water through the permeable capillaries.

This explains in part the difference between shock due to trauma in which increased capillary permeability is an initial derangement *and shock due to hemorrhage in which capillaries begin to leak* late due to anemic anoxemia. Shock will be delayed more in the latter, will be more amenable to treatment, and irreversibility will be postponed longer.

These are illustrations of the effects of injury on normal physiological processes and the *great reserves present to protect and restore* vital activities.

This clinico-pathologic picture of shock then is a synchronized dynamic mechanism invoked to sustain life—should it fail, irreversible shock ensues with peripheral vascular failure and blood is pooled in the skin. *Although the causes are varied, the essential factor is* a reduction in the circulating blood volume which results in disturbances of:

1. The central nervous system—caused by stagnant anoxia
   (a) Peripheral—dulled sensation
   (b) Central—mental torpor, or delirium
2. The sympathetic nervous system—caused probably by anoxia, sensory stimuli (in neurogenic shock), and reflex compensatory mechanisms
   (a) *Pale skin, sweating, and low body temperature*
3. The respiratory center—caused by stagnant anoxia
   (a) Rapid, shallow breathing
   (b) *Irregular breathing (of the Cheyne-Stokes type); sighing* or stertorous breathing
4. The circulatory system
   (a) Cardiac—caused by diminished blood volume
      (1) Rapid, feeble pulse

The third step was to prove that if these various traumas were accompanied by a significant increase in the size and weight of the injured part, such increase was due to blood or blood plasma. After carefully studying the fluid from an injured part they found that, after mild trauma to an extremity, it contained a few red blood cells but was mostly plasma; after severe trauma to an extremity, the fluid consisted of whole blood; after burning an extremity, the fluid was clear and resembled pure plasma. After trauma to the intestines, the fluid contained some red blood cells but was mostly plasma. The fluid was in every case studied for chloride content, sugar content, and nonprotein nitrogen content and was found to be identical with normal blood plasma, although recent studies show a decrease in sodium and an increase in potassium.

The fourth step in the series of experiments consisted in studying the dogs with traumatized extremities at autopsy. Contrary to the opinions of previous observers, the great splanchnic areas and the intestinal tract were found to be pale and bloodless and the muscles in other parts of the body were found to have lost fluid. If a general toxin had been the cause of the shock, the reverse would have been the case.

Lastly, it seemed that the entire picture resembled one of hemorrhage, so the experimenters bled their animals of small amounts of blood at hourly intervals. They found that the results of taking whole blood are practically the same as those which follow trauma to an extremity. The results of taking pure plasma are practically the same as the results of burning an extremity.

Normally there is a free exchange of salts and substances of small molecular weight between the blood stream and the tissue spaces. This is not true of colloids, which are mainly proteins, because the blood vessels are normally impermeable to them. This is important, for the suction force (osmotic pressure) for the plasma normally counteracts the hydrostatic pressure of the capillaries. Since the fluid in the injured extremities has a protein content equal to that of the blood plasma, and since normally these proteins cannot go through the capillary wall, the proteins must have passed through the capillary wall because its permeability has been increased by capillary damage. Thus there results an osmotic pressure in the tissues equal to that of the blood, so there is no reabsorption of fluid from the injured extremity. The dehydration of the blood and the fall in the blood pressure does, to be sure, raise the effective osmotic pressure of the blood, and fluid is drawn in from healthy tissues all over the body, but this fluid is lost from the capillaries in the injured area. *Therefore, the loss of plasma proteins is the most important factor in the production of shock.* It is easy to understand, now, why shock due to trauma is more difficult to treat than is uncomplicated hemorrhage. In the latter we tie off the bleeder and restore the blood loss. After trauma, any procedure which increases hydrostatic pressure causes more loss of fluid through the injured, permeable capillaries. This is especially true after the injection of a crystalloid fluid, such as physiological salt solution. (Chapter 11.)

These experiments seem to clarify at least the cause of shock when induced by trauma to an extremity. However, it is well known that these explanations do not account for all forms of shock seen clinically. *There is one common denominator and that is a reduction in the circulating blood volume with loss of blood plasma.* In cases where the blood volume is reduced without a leakage of plasma from injured capillaries there is undoubtedly a loss of fluid to some extent, but this is so small that symptoms are transient. *Loss of plasma increases the hematocrit reading and accounts for the sustained symptoms and even death.* The mechanisms by which this reduction in circulating blood occurs are varied and each has been advanced as the cause of shock. The assembled evidence shows that any or all of these may be important in the cause of shock.

RECENT EXPERIMENTAL WORK

The Civil War and World War I provided an enormous stimulus for the study of shock. World War II with all of its modern scientific instruments of precision and perspicacious investigators also instigated the present quest for an answer to the prob

Crile thought that the circulatory failure was due to an exhaustion of the vasomotor center and the brain cells as a result of afferent impulses deluging the center. Mummery also believed this, but Porter, Mann, Ewing, and Janeway, Parsons and Phemister, and Blalock have shown that very prolonged stimulation of somatic nerves in mammals does not bring on circulatory failure.

Meltzer thought shock to be due to reflex inhibition, but Howell thought it due to stimulation of the cardioinhibitory centers.

Heidenhain in 1891 found that peptone, when injected intravenously into certain animals, produced marked exhaustion. Dale and Laidlow in 1910 described the paralyzing effect of histamine upon the capillaries. Dale and Richards in 1918 demonstrated so-called histamine shock.

It remained for the great physiologist, W. B. Cannon, to evolve the theory of the causation of shock that was accepted as the final word. Briefly stated, he contended that shock was produced by a metabolite (histamine) which injured the capillaries, causing them to dilate and remain paralyzed in that markedly dilated and therefore more permeable condition. During World War I he showed that if a soldier had a mutilated limb and a tourniquet was applied, shock did not follow, but if the tourniquet was released, shock ensued. He showed that traumatic shock was not a nervous reaction, for the spinal cord of animals could be divided and yet shock would follow. He thought he had proved, with the aid of Bayliss, that traumatic shock was not due to loss of blood in the part traumatized. It was his idea that shock may be the result of a dilation of the whole capillary system; that this capillary dilation is produced by a poisonous substance originating in the injured area and carried by the circulating blood; that the poisonous substance arises from proteolysis in the injured area; and that the circulatory failure in shock is due to a trapping of blood in the great capillary beds of the body, principally the splanchnic and muscular areas, and to the exudation of plasma through the permeable capillary walls. In other words, an individual bleeds to death in his own capillaries and that capillary blood may have an erythrocyte count which is 2 to 3 million higher than venous blood.

The work of Parsons and Phemister and of Blalock and his associates seems to rationalize the conflicting opinions of the causation of shock and to bring new light to this important subject.

First, the theory of a toxic substance causing shock seems to be partially disproved. Blood from an injured extremity, when absorbed by a dog or when injected into a normal dog, produces no symptoms. Blood from parts which have been traumatized by various means may be injected without producing any of the symptoms of shock. Traumatized muscle may be transplanted in various ways into normal animals without any symptoms of shock. The injection of histamine produces alterations in blood volume, plasma, red blood cell count, hemoglobin, and chloride content similar to those which occur after trauma, but the course of events is different. Hemorrhage and various types of trauma cause, first, a significant decrease in the output of the heart, and later, a drop in blood pressure. On the other hand, the injection of histamine causes first a decline in blood pressure and later a decrease in the cardiac output.

The second problem undertaken for solution was to determine whether or not there was a decrease in blood volume in shock, and if so, where this blood had gone. To solve this problem, dogs were anesthetized and their extremities were traumatized. In every case after sufficient trauma had been produced to bring about symptoms of shock, the traumatized extremities weighed approximately 3½ per cent of the body weight more than the normal extremities. Next, these experimenters decided to note the effect of burns upon the animal in the production of shock. They burned an extremity of an anesthetized dog and found that here, too, the burned leg weighed two and three-fourths per cent of the body weight more than the normal extremity. They next produced injuries to the intestines and here again found a marked increase in the size of the intestinal loops and mesentery and also a great increase in free peritoneal fluid.

Ischemic muscle necrosis, crushing injury, or crush syndrome was observed during World War II following air raids when people were pinned beneath falling debris from demolished buildings. Bywaters believes that plasma loss may play a role but renal failure due to the absorption of substances from the crushed muscle (myohemoglobin) is chiefly responsible. Others believe that extravasation of blood into body tissue, transfusion reaction due to incompatability, and crush syndrome are all related since they may produce hemoconcentration, hypotension, acidemia, and oliguria with acid urine containing creatinine. It is true that in crush syndrome there is myohemoglobinuria, whereas in the others there is usually hematuria and hemoglobinuria.

In this review many pertinent experiments have not been discussed. They may be found in the selected references at the conclusion of the chapter. It is the data more directly applicable to common clinical problems which has been summarized rather than the esoteric and turgid discussions of the pure researchers.

CLINICAL CAUSES OF SHOCK

Any sudden injury, local or general, functional or organic, mechanical, chemical, thermal or bacterial, accompanied by oligemia, hydremia, or plethora may lead to widespread dynamic adjustments to preserve that without which life is impossible—adequate blood and oxygen. To speak of the causes of shock therefore is to speak of all injuries to the body, because any kind of trauma, if sudden and severe enough, requires bold defensive changes to sustain life.

The injury which causes shock may have a single effect easy to interpret or it may have many consequences. For example, postoperative shock may be due to loss of blood, trauma to tissue, or prolonged anesthesia. It is easy to understand the first and second, but the third, anesthesia, may in turn produce shock through anoxemia, cardiac or respiratory failure, vasodilation, stagnant anoxemia due to prolonged immobilization, or shock from prolonged anesthesia alone. Infection may produce shock as a terminal event through toxic capillary stasis with loss of plasma and stagnant anoxemia, or through toxic myocarditis with cardiac incompetency, or through multiple septic emboli producing anoxemia plus vascular stasis; or, because of its extent, it may act as a burn with enormous loss of plasma through dilated and permeable capillaries; and lastly because of its suddenness and the amount of the antigen, the effect may include cerebral and cardiac damage with a swift and dramatic course as is seen in septic abortion, sudden flooding of the peritoneal cavity from a large perforation of a viscus—indeed this may simulate the injection of a syringe full of virulent streptococci directly into a large vein. In the list of clinical causes the effects will be mentioned briefly; then we shall discuss the effects in greater detail.

The clinical states which more commonly lead to shock may be listed as follows.

1 Loss of whole blood or plasma or both externally into body cavities or into tissues due to
   - (a) Loss of whole blood from severed heart or vessels due to
     - (1) Direct injury
     - (2) Operative blood loss
     - (3) Pathological changes in blood vessels such as ruptured aneurysm

lem. Although many questions remained unanswered, from it all has come some important observations which helped save lives during the World War II and which may be applied now in peacetime.

Moon and his colleagues speak of circulatory failure of capillary origin in which the gross and microscopic changes seen at post mortem show evidence of capillary damage such as dilatation, stasis, petechial hemorrhages, edema, and effusions present in extensive visceral areas, all due to capillary atony and tissue anoxia. They aver that the effects of hemorrhage and shock are entirely different, especially since in the former there is hemodilution and in the latter hemoconcentration. However, anoxia finally causes injury to capillary endothelium with leakage of plasma so that edema and hemoconcentration may be an end result. In this way shock begins with damage to capillary endothelium and hemorrhage ends that way. Wood and Blalock showed that hemoconcentration (erythrocytosis) per se does not cause shock. Fine, Frank, and Seligman believe that hemorrhagic shock is not apt to result in an irreversible state as rapidly as tourniquet shock. They found that transfusions may be curative even after the blood pressure remains at 30 mm. Hg. for hours, whereas transfusion is not curative if the blood pressure remains below 80 mm. Hg. for hours in tourniquet shock. They do not believe that the anoxemia in shock causes widespread capillary leakages. They used synthesized radioactive sulfur, bromine, and iodine in plasma proteins to prove their point. Plasma is lost especially in the injured area but irreversibility is due to decreased volume flow and velocity of the flow through the capillaries with a resulting cumulative adverse effect on vital organs or tissues, particularly the liver.

Richards introduced a long ureteral catheter into a median basilic vein, then along the axillary, then the subclavian, and into the right atrium. Forssmann had done this on himself more than ten years before. By this technique the pressure of blood in the right atrium and the total volume flow of blood or cardiac output may be measured. Shock was studied in this manner in human beings. The following observations were recorded: (1) there is an inadequate venous return of blood to the heart with diminished cardiac output; (2) a deficit in circulating blood volume is responsible.

Freeman believes that vasoconstriction may be an initiating factor in shock, whereas Wiggers criticizes this theory on the following counts: namely, that it has not been proved that the total resistance to the outflow of blood from the aorta is increased in early shock; that shock has not been produced by prolonged vasoconstriction due to stimulation of the sympathetics; that experimental and clinical hypertension in which total peripheral resistance is increased does not result in shock, and, finally, that adrenalin which is thought to cause shock in large doses actually produces deleterious effects on the coronary circulation and the heart. However, it is nevertheless possible to produce adrenalin shock without demonstrable coronary impairment.

Heymans demonstrated that the continuous secretion of epinephrine is reflexly controlled by afferent aortic and sinus nerves. Thus the carotid sinus is a nervous mechanism which controls the circulation directly through pressure changes and indirectly through chemical regulation. Weiss and his co-workers described three main types of cardiovascular response to carotid sinus stimulation: (a) *vagal*, characterized by marked asystole or sudden slowing of the heart rate, with or without marked fall in the arterial blood pressure; (b) *depressor*, characterized by fall in the arterial blood pressure without cardiac slowing; and (c) *cerebral* due to changes in cerebral circulation without slowing of heart rate and without a fall in arterial blood pressure. They found patients with spontaneous attacks of dizziness, weakness, and unconsciousness with or without convulsion. Pressure over the carotid sinus reproduced these symptoms. Denervation of the carotid sinus resulted in cure.

Barrow and Rhoads studied blast concussion injury abroad and experimentally here. Blast waves are irregular with many eddies in their periphery; they are reflected from surface to surface and are subject to augmentation or neutralization by other waves. It is the positive wave rather than the negative that causes most of the injuries to the lungs, heart, intestine, eyes, ears, and other organs. Negative wave may have some influence. In water there is only one wave and it is positive.

Ischemic muscle necrosis, crushing injury, or crush syndrome was observed during World War II following air raids when people were pinned beneath falling debris from demolished buildings. Bywaters believes that plasma loss may play a role but renal failure due to the absorption of substances from the crushed muscle (myohemoglobin) is chiefly responsible. Others believe that extravasation of blood into body tissue, transfusion reaction due to incompatability, and crush syndrome are all related since they may produce hemoconcentration, hypotension, acidemia, and oliguria with acid urine containing creatinine. It is true that in crush syndrome there is myohemoglobinuria, whereas in the others there is usually hematuria and hemoglobinuria.

In this review many pertinent experiments have not been discussed. They may be found in the selected references at the conclusion of the chapter. It is the data more directly applicable to common clinical problems which has been summarized rather than the esoteric and turgid discussions of the pure researchers.

CLINICAL CAUSES OF SHOCK

Any sudden injury, local or general, functional or organic, mechanical, chemical, thermal or bacterial, accompanied by oligemia, hydremia, or plethora may lead to widespread dynamic adjustments to preserve that without which life is impossible—adequate blood and oxygen. *To speak of the causes of shock therefore is to speak of all injuries to the body,* because any kind of trauma, if sudden and severe enough, requires bold defensive changes to sustain life.

The injury which causes shock may have a single effect easy to interpret or it may have many consequences. For example, postoperative shock may be due to loss of blood, trauma to tissue, or prolonged anesthesia. It is easy to understand the first and second, but the third, anesthesia, may in turn produce shock through anoxemia, cardiac or respiratory failure, vasodilation, stagnant anoxemia due to prolonged immobilization, or shock from prolonged anesthesia alone. Infection may produce shock as a terminal event through toxic capillary stasis with loss of plasma and stagnant anoxemia, or through toxic myocarditis with cardiac incompetency, or through multiple septic emboli producing anoxemia plus vascular stasis; or, because of its extent, it may act as a burn with enormous loss of plasma through dilated and permeable capillaries; and lastly because of its suddenness and the amount of the antigen, the effect may include cerebral and cardiac damage with a swift and dramatic course as is seen in septic abortion, sudden flooding of the peritoneal cavity from a large perforation of a viscus—indeed this may simulate the injection of a syringe full of virulent streptococci directly into a large vein. In the list of clinical causes the effects will be mentioned briefly; then we shall discuss the effects in greater detail.

The clinical states which more commonly lead to shock may be listed as follows:

1 Loss of whole blood or plasma or both externally into body cavities or into tissues due to

(a) Loss of whole blood from severed heart or vessels due to

(1) Direct injury

(2) Operative blood loss

(3) Pathological changes in blood vessels such as ruptured aneurysm

(4) Heart rupture from coronary infarct
(5) Ruptured ectopic pregnancy
(6) Bleeding peptic ulcer
(7) Post-partum hemorrhage, etc.

(b) Burns, freezing—loss of plasma
(c) Trauma to body—loss of whole blood and plasma
(d) Trauma to intestines—loss of plasma chiefly
(e) Sudden removal of intra-abdominal pressure—loss of plasma and stagnation of blood in large veins (stagnant anoxemia)
(f) Fracture of long bones—loss of blood and plasma, rarely fat embolism
(g) Prolonged application of tourniquet—loss of plasma and stagnation of blood in large veins

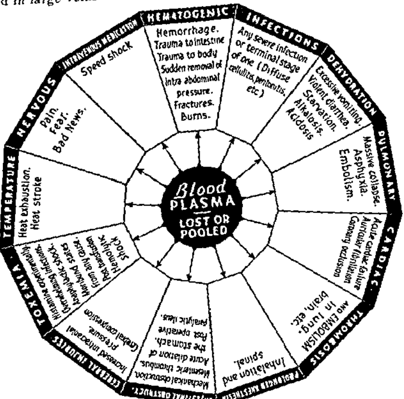

Fig. 108.—Diagram indicating some of the clinical causes of shock. In each instance blood plasma is lost through injured capillaries or pooled in dilated capillaries. In the latter instance, due to dilatation and stagnant anoxia, the capillaries become more permeable and here, too, plasma may be lost

(h) Crushing injuries, compression syndrome, extravasation of blood into tissues from any cause—loss of blood and plasma plus anuria and its effects
(i) Blast concussion—loss of blood and plasma
(j) Radiation sickness due to plasma loss into irradiated areas (Atomic bomb produced this in an acute fatal form)

2. Infection—Any severe extensive, or terminal stage of infection; sudden flooding with antigen caused by gas bacillus, streptococcus, staphylococcus in diffuse cellulitis, peritonitis, especially after perforation of a large ulcer or base of appendix or bullet wound—loss of plasma, stagnant anoxemia
3. Dehydration and starvation due to excessive vomiting, violent diarrhea, and accompanied by acidosis and alkalosis—stagnant anoxemia from hemoconcentration, anuria, toxic effect on capillaries also act as intensifying factors in other causes of shock such as hemorrhage and burns with local fluid loss and oligemia

4. Pulmonary mediastinal causes
   (a) Lungs
      (1) Embolism—due to sudden anoxemia, blockage of main arterial paths with resultant cardiac inadequacy, trapping of large amount of blood on the venous side due to decreased vis a tergo, and passive congestion
      (2) Massive collapse—chiefly anoxic anoxemia
      (3) Anoxemia from any cause—anoxic, anemic, stagnant, histiotoxic, or combinations
      (4) Paradoxical respiration
   (b) Pleura
      (1) Hemothorax—loss of blood and anoxia
      (2) Tension pneumothorax—anoxia venous stasis
   (c) Mediastinal shift or flutter—anoxia, venous stasis
5. Cardiac
   (a) Acute cardiac failure
   (b) Auricular fibrillation
   (c) Coronary occlusion
   (d) Cardiac tamponade

   Inability of heart to pump normal amount of blood because of weakness in heart itself, inability of heart to fill properly because of tamponade, inadequate amount of blood reaches heart, all of which results in decreased circulating blood volume due to pooling of blood on the venous side with stagnant anoxemia
6. *Thrombosis and embolism*
   (a) Mesenteric—loss of plasma and blood, bowel obstruction
   (b) Pulmonary—loss of plasma, anoxemia
   (c) Cerebral—cerebral compression with failure of respiratory, vasomotor, and cardiac centers
7. Anesthesia
   (a) Prolonged—probably due to stagnant anoxemia as well as anoxic anoxemia and reduction of circulating blood volume due to pooling; also cardiac and respiratory failure
   (b) Spinal—probably due to peripheral vasodilatation plus stagnation of blood in immobile extremities leading to reduced circulating blood volume and stagnant anoxemia
8. Acute intestinal obstruction
   (a) Postoperative
   (b) Paralytic ileus
   (c) Mechanical obstruction
   (d) Mesenteric thrombosis
   (e) Acute dilatation of stomach

Many factors involved in acute intestinal obstruction including dehydration with hemoconcentration and stagnant anoxemia, loss of plasma into peritoneal cavity, pooling of *blood into obstructed loops, anoxic anoxia due to interference* of descent of diaphragm due to distention, toxic factors.

9. Cerebral injuries
   (a) Increased intracranial pressure
   (b) Cerebral compression

Paralysis of vasomotor, cardiac, and respiratory centers due to pressure and ischemia; also loss of blood and plasma into brain tissue, skull, and scalp

10. Toxemia
   (a) Histamine, peptone, tissue extracts of muscle, adenylic acid, potassium injections experimentally—capillary poisons with loss of plasma and pooling in capillaries with anoxia

(4) Heart rupture from coronary infarct
(5) Ruptured ectopic pregnancy
(6) Bleeding peptic ulcer
(7) Post-partum hemorrhage, etc.

(b) Burns, freezing—loss of plasma
(c) Trauma to body—loss of whole blood and plasma
(d) Trauma to intestines—loss of plasma chiefly
(e) Sudden removal of intra-abdominal pressure—loss of plasma and stagnation of blood in large veins (stagnant anoxemia)
(f) Fracture of long bones—loss of blood and plasma, rarely fat embolism
(g) Prolonged application of tourniquet—loss of plasma and stagnation of blood in large veins

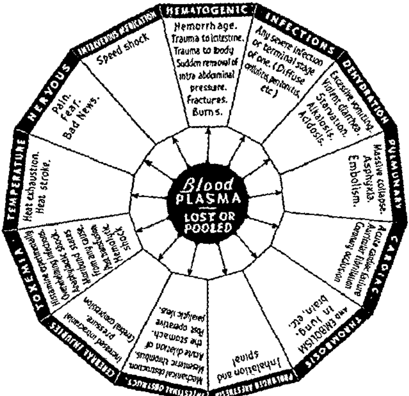

Fig 108.—Diagram indicating some of the clinical causes of shock. In each instance *blood plasma is lost through injured capillaries or pooled in dilated capillaries.* In the latter instance, due to dilatation and stagnant anoxia, the capillaries become more permeable and here, too, plasma may be lost.

(h) Crushing injuries, compression syndrome, extravasation of blood into tissues from any cause—loss of blood and plasma plus anuria and its effects
(i) Blast concussion—loss of blood and plasma
(j) Radiation sickness due to plasma loss into irradiated areas (Atomic bomb produced this in an acute fatal form)

2. Infection—Any severe extensive, or terminal stage of infection; *sudden flooding* with antigen caused by gas bacillus, streptococcus, staphylococcus in diffuse cellulitis, peritonitis, especially after perforation of a large ulcer or base of appendix or bullet wound—loss of plasma, stagnant anoxemia
3. Dehydration and starvation due to excessive vomiting, violent diarrhea, and accompanied by *acidosis and alkalosis—stagnant anoxemia from* hemoconcentration, anuria, toxic effect on capillaries also act as intensifying factors in other causes of shock such as hemorrhage and burns with local fluid loss and oligemia

total blood volume is unchanged, the circulating blood volume greatly reduced. The blood is pooled in the splanchnic vessels, which, because of their dilatation and the accompanying anoxia, become more permeable. In some types of shock the vasoconstrictors may be overactive.

Neurogenic shock due to fear, cold, or adrenalin may be explained by this response. Vasoconstriction produced by prolonged stimulation of the sympathetic nervous system in the normal animal leads to a decrease in the circulating blood volume. Following complete sympathectomy this does not occur. Vasoconstriction occurs in certain regions or

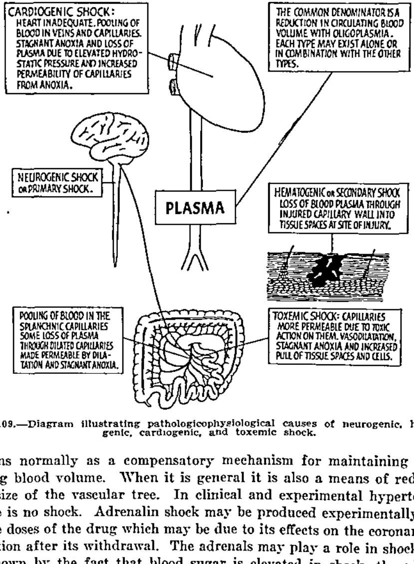

Fig. 109.—Diagram illustrating pathologicophysiological causes of neurogenic, hematogenic, cardiogenic, and toxemic shock.

organs normally as a compensatory mechanism for maintaining circulating blood volume. When it is general it is also a means of reducing the size of the vascular tree. In clinical and experimental hypertension there is no shock. Adrenalin shock may be produced experimentally with large doses of the drug which may be due to its effects on the coronary circulation after its withdrawal. The adrenals may play a role in shock; this is shown by the fact that blood sugar is elevated in shock; the adrenal cortex assists in regulating electrolyte balance, especially sodium and potassium, and influences the permeability of cells, including the capillaries; adrenalectomy causes death due to capillary atony, dilatation,

(b) Overwhelming infections
(c) Anaphylactic shock—bronchiolar constriction with anoxic anoxemia and capillary atony
(d) Hemolytic shock after blood *transfusions with incompatible blood*—*hemolysis*, capillary leakage, hemoconcentration, anuria
(e) Crush *syndrome*
(f) Drugs and poisons—may act on cell or capillaries

11. Moribund states from any cause—produce myocardial impairment due to primary (the heart itself), secondary (the result of infections or toxins), or tertiary (the result of hypotension) causes. Terminal shock is accompanied by vasodilation and capillary atony; there may be vasodilation, or vasoconstriction, the former leading to arteriolar and the latter to capillary stasis with a decrease in circulating blood volume with a reduction of the amount of blood returning to the heart and cardiac inadequacy
12. *Shift of blood into large veins*
    (a) In aviation—acceleration shifts blood into large veins (high positive) and the centrifugal effect *prevents blood from reaching right* auricle—also a drop in carotid and jugular pressure
    (b) *Sudden release of intra-abdominal pressure*
13. High or low environmental temperature
    (a) Heat exhaustion, "overheating"—heat retention, *since it cannot be lost* by radiation or evaporation if environmental temperature exceeds body temperature and is saturated with moisture—dehydration and loss *of sodium* chloride with vascular collapse
    (b) Heat stroke, "sun stroke"—heat retention due to loss of heat control, high fever, peripheral vasodilation with collapse
    (c) Freezing shock, cold exhaustion—fall in body temperature, depression of dissociation of oxyhemoglobin with anoxemia, peripheral vasoconstriction, capillary stasis decrease in circulating blood volume
14. Nervous
    (a) Severe pain—nociceptive stimuli may add to shock
    (b) Fear
    (c) "Bad news"
    (d) Overwhelming emotions of any type
    (e) Carotid sinus stimulation
15. Plethora, hydremic plethora, "speed shock"
    (a) Large quantities of blood given very rapidly when there has not been a *proportionate loss*
    (b) Rapid introduction of intravenous medication in great amounts
    (c) *Intravenous medication given* under pressure

Vascular system unable to expand quickly enough for the great increase in blood *volume; more blood in right heart* than can be pumped to the lungs with resultant cardiac incompetency; or multiple hemorrhages from rupture of small *vessels throughout the body and* blood extravasation syndrome with anuria

PATHOLOGICOPHYSIOLOGIC CAUSES OF SHOCK

Neurogenic or Primary Shock

Neurogenic or primary shock comes on immediately and is supposed to be due to an inhibition of vasoconstrictor fibers (and stimulation of undemonstrated *vasodilators) caused by prolonged activity* of the sympathetic nervous system. There is a decrease in vasomotor tone, with an early fall in blood pressure; then, later, a decreased cardiac *output*. The

reduced circulating blood volume. In this variety of shock, however, there is an actual loss of whole blood, plasma, or both, externally, into body cavities or into the tissues. As a result of this loss of blood volume there is cardiac insufficiency (low venous pressure in the vena cava causes the right atrium to be incompletely filled) and a consequent fall in arterial pressure. *In recovery from shock after blood or blood substitutes* have been given there is a rise in blood pressure before blood volume has been completely restored due to more adequate filling of right atrium. It is called secondary shock because it takes some time to manifest itself. This will vary with the amount of blood or plasma lost and the rapidity of its emergence from the circulation. However, when it does appear, the complete clinical picture is apparent instantly and dramatically. That is to say, a patient may leave the operating room in apparently excellent condition and all laboratory tests, including hematocrit, plasma protein, and blood counts may be normal, yet on arriving in his room he may suddenly go into a state of profound shock and may die unless measures are used promptly to restore the circulating blood volume.

If a frog's web is stroked gently, the capillaries will open; then new ones will be seen. After a time the web will get so thick that one cannot see through it. We learned in Chapter 3 that this is the exudative response to injury. This is due to a loss of plasma. If the stroking continues, capillaries will rupture and there will be loss of whole blood; the web will then be flooded with red blood cells. This experiment illustrates the cause of blood and plasma loss. If the area of the web is greatly exaggerated and if trauma of any kind is inflicted, then sufficient plasma will be lost to produce shock. Tourniquet shock results after a tourniquet is released from an extremity. The surface of a leg represents roughly 18 per cent of the body surface; the interior of the leg filled with muscles which contain over 700 capillaries per cubic millimeter is a veritable lake of vascular space. When a tourniquet is applied, no blood enters or leaves the extremity. *Capillaries are dilated* due to paralysis of vasoconstrictors and the accumulation of metabolites (H substances) in the tissues. Capillaries are more permeable because they are dilated and because the endothelial cells are damaged by anoxia. When the tourniquet is released, shock ensues; it will be more profound the longer the tourniquet is on prior to its release because capillaries will be damaged more If the tourniquet is released at intervals, if the leg is packed in ice if firm pressure is applied to the extremity by elastic bandage, shock will be less severe when the tourniquet is removed because less plasma will be lost.

Fine and his co-workers tagged plasma with radioactive substance and found that plasma is lost in shock at the site of injury but not all over. As shock deepens, about one-fifth of capillary blood becomes stagnant. The progressive decline in shock is due *principally to a fall of*

stasis, and peripheral vascular stagnation. *If there is sudden and prolonged vasoconstriction, shock occurs. This type may also be seen as a result of stimulation of vasomotor center by chemical or mechanical agents such as local anesthesia and operation in upright position.* If the vasoconstriction is slow in evolving as in hypertension, shock does not occur. This is true in hemorrhage, brain tumor, or any other factor which may destroy life. When compensatory mechanisms have a chance to adapt the organ or organism to its handicaps, symptoms may be few and obscure. When the are found to act suddenly, symptoms are severe and prominent. It is well to remember that vasodilation as seen in spinal anesthesia leads to arteriolar stasis and will be benefited by adrenalin. Vasoconstriction leads to capillary stasis and will not be helped by the drug. This is seen in hematogenic shock where vasoconstriction is an attempt to compensate for the reduced blood volume. The arterioles are constricted and the capillaries are dilated and lose blood plasma. Capillary pressure rises due to an increase in the proportion of blood cells and the resulting viscosity, which slows the circulation and permits a greater transudation of fluid from the vessels. A vicious circle is thereby induced until the blood pressure falls to a critical level; then vasodilatation occurs and death may follow. Neurogenic shock is transient as a rule. Fear, anger, "bad news," or pain may cause it.

W. B. Cannon *found that soldiers who were hungry or cold would go into shock with a small wound but that soldiers who were warm and well-fed could stand much pain. If the blood pressure is low, the heart will not have sufficient blood to pump and stasis will occur in the capillary beds, and ultimately secondary shock may result due to increased permeability of the capillaries from stagnant anoxia. In spinal anesthesia the constrictor response to hemorrhage is abolished and therefore hemorrhage and shock are apt to occur.*

Neurogenic shock is apt to be due to *carotid sinus stimulation. Depressor type syncope* is seen in predisposed *persons with a tendency to* postural hypotension *after prolonged bed rest, debilitating conditions such as fatigue, fasting, severe anemia, or other disease, standing at attention for long periods, or standing in crowds. Syncope due to standing in crowds or standing at attention may be due to pooling of blood in the veins of the legs and abdomen. The heart rate is not slowed;* the blood *pressure is low. Vagal type. Syncope may occur* with slowing of the heart *or asystole and consequent fall in blood pressure. Cerebral type. This manifests itself without slowing of heart or fall in blood pressure but with convulsions and hyperpnea.* This type is probably due to a disturbance of the blood supply to the carotid body.

Hematogenic or Secondary Shock

Hematogenic or secondary shock occurs, as the name implies, from loss of blood plasma. This is a misnomer because all shock is due to a

reduced circulating blood volume. In this variety of shock, however, there is an actual loss of whole blood, plasma, or both, externally, into body cavities or into the tissues. As a result of this loss of blood volume there is cardiac insufficiency (low venous pressure in the vena cava causes the right atrium to be incompletely filled) and a consequent fall in arterial pressure. In recovery from shock after blood or blood substitutes have been given there is a rise in blood pressure before blood volume has been completely restored due to more adequate filling of right atrium. It is called secondary shock because it takes some time to manifest itself. This will vary with the amount of blood or plasma lost and the rapidity of its emergence from the circulation. However, when it does appear, the complete clinical picture is apparent instantly and dramatically. That is to say, a patient may leave the operating room in apparently excellent condition and all laboratory tests, including hematocrit, plasma protein, and blood counts may be normal, yet on arriving in his room he may suddenly go into a state of profound shock and may die unless measures are used promptly to restore the circulating blood volume.

If a frog's web is stroked gently, the capillaries will open; then new ones will be seen. After a time the web will get so thick that one cannot see through it. We learned in Chapter 3 that this is the exudative response to injury. This is due to a loss of plasma. If the stroking continues, capillaries will rupture and there will be loss of whole blood; the web will then be flooded with red blood cells. This experiment illustrates the cause of blood and plasma loss. If the area of the web is greatly exaggerated and if trauma of any kind is inflicted, then sufficient plasma will be lost to produce shock. Tourniquet shock results after a tourniquet is released from an extremity. The surface of a leg represents roughly 18 per cent of the body surface; the interior of the leg filled with muscles which contain over 700 capillaries per cubic millimeter is a veritable lake of vascular space. When a tourniquet is applied, no blood enters or leaves the extremity. Capillaries are dilated due to paralysis of vasoconstrictors and the accumulation of metabolites (H substances) in the tissues. Capillaries are more permeable because they are dilated and because the endothelial cells are damaged by anoxia. When the tourniquet is released, shock ensues; it will be more profound the longer the tourniquet is on prior to its release because capillaries will be damaged more. If the tourniquet is released at intervals, if the leg is packed in ice, if firm pressure is applied to the extremity by elastic bandage, shock will be less severe when the tourniquet is removed because less plasma will be lost.

Fine and his co-workers tagged plasma with radioactive substance and found that plasma is lost in shock at the site of injury but not all over. As shock deepens, about one-fifth of capillary blood becomes stagnant. The progressive decline in shock is due principally to a fall of

actively circulating plasma rather than to a continued loss of this vital fluid. After it has been replaced, velocity flow must be restored before vital tissue processes are lost. The truth of this statement is confirmed at autopsy in patients dying of shock. Often enormous quantities of plasma and blood are introduced, even under high positive pressure. The volume is thereby completely replaced, but if the heart does not circulate it, the body cavities will be full of plasma and actually hasten death. Anoxemia, from any cause, will increase capillary permeability in shock; this is stagnant or anemic anoxia—all capillaries begin to leak under such conditions.

Secondary shock is due to a loss of blood plasma into the tissues. Hematocrit readings and plasma protein studies show this to be true because there is a great decrease in plasma and an increase in cells. This is perhaps the only way in which shock due to hemorrhage can be differentiated from shock due to loss of blood plasma. However, if bleeding is long continued, enough plasma will be lost to reduce osmotic pressure in the capillaries. They will also become more permeable due to anoxia (caused by the constricted arterioles and reduced volume flow as well as the hemodilution). Capillaries become permeable and fluid is lost in the tissues with resulting edema (Chapter 11). Finally in hemorrhage there may be hemoconcentration. Thus traumatic shock begins with capillary injury, whereas hemorrhagic shock ends this way.

Erythremia in shock may be due in part to splenic contraction. Page and Glasser found that 50 per cent of the increase in red blood cells results from this cause in intestinal manipulation shock and 65 per cent in tourniquet shock. Perhaps the increase in adrenalin during shock may be partly responsible for splenic contraction.

Blood viscosity is increased due to loss of fluid into the injured tissues; this increases the tendency for pooling in the hyporeactive capillaries reducing the circulating blood volume.

By referring to the chapter on hemorrhage we see that the clinical symptoms of shock due to loss of whole blood and shock due to loss of plasma are the same. However, in hemorrhage, when bleeding is controlled symptoms abate and transfusion is curative even after the blood pressure has been as low as 30 mm. Hg for hours. This is not true of traumatic shock in which the capillaries continue to lose plasma twenty-four to forty-eight hours after the injury. Even in severe trauma, where capillaries are actually ruptured, the loss of red blood cells soon ceases due to clotting, but plasma continues to be lost.

Cardiogenic Shock

In cardiogenic shock there is first a cardiac inadequacy and then a fall in arterial blood pressure due to a pooling of the blood. The patient is cyanotic and the veins are distended (especially in the neck). Clinically this type is seen in auricular fibrillation, coronary occlusion, and

acute cardiac failure and in cardiac thrombosis and embolism. There is no actual loss of blood, yet the quantity of circulating blood is suddenly reduced. Venous pressure is greatly increased, venules and capillaries are greatly dilated, arterioles are constricted. Soon leakage of plasma occurs, for dilatation and increased permeability of capillaries go hand in hand and stagnant anoxia enhances the process. In addition, the dyspnea which accompanies cardiac failure increases the negative pressure in the thorax (see Chapter 19). Thus there is an increase in pulmonary venous pressure and also an increase in the negative pressure within the thorax. This results in pulmonary edema and increased anoxia.

Toxemic Shock

Toxemic shock (vasogenic) is due to a toxin in the blood. This form of shock may be produced in animals experimentally by injecting histamine. Most observers believe that the death of the injured soldier which Cannon describes as having occurred after the release of a tourniquet on a mangled extremity was caused by a sudden rush of blood into the damaged capillaries, with a great loss of blood plasma. Tourniquets placed on extremities in experimental animals for any length of time will produce shock when released. This, according to Allen, cannot be entirely explained on the theory of loss of blood plasma. The capillaries are more permeable (due to paralysis of vasoconstrictors, local asphyxia, and capillary damage caused by stasis), but the tissue spaces and cells are rendered more able to accept more plasma by the toxic factor. After injection of histamine the blood becomes more concentrated as a result of a loss of "free" water and the muscles gain water (Robinson and Parsons). Thus the old idea of a patient "bleeding to death in his own capillaries" is only partially correct, for in addition he loses plasma and water into the tissues. *Far from being obsolete, this theory undoubtedly explains the permeability of capillaries in infections with great edema and loss of plasma into the affected area—from the simple localized swelling of a boil to the widespread loss of plasma in peritonitis.* Perhaps also in extensive burns this theory may explain in part the cause of local and general capillary permeability. It is perhaps a causative factor in infection, dehydration, moribund states from any cause, and posttransfusion shock.

Many of the chemicals used to produce toxemic shock experimentally have been mentioned under Clinical Causes of Shock. There is reason to believe that toxins play a role because of recent experimental and clinical observations. Some of these should be reviewed. After crushing injuries or burns a sludge forms in the injured vessels; this may be initiated by local tissue toxins and may contribute to a toxemia by multiple emboli or the release of toxic substances from the "sludge." Potassium is increased in shocked animals probably due to damage of tissue cells. However, its toxicity increases six to nine times. This is not true of

actively circulating plasma rather than to a continued loss of this vital fluid. After it has been replaced, velocity flow must be restored before vital tissue processes are lost. The truth of this statement is confirmed at autopsy in patients dying of shock. Often enormous quantities of plasma and blood are introduced, even under high positive pressure. The volume is thereby completely replaced, but if the heart does not circulate it, the body cavities will be full of plasma and actually hasten death. Anoxemia, from any cause, will increase capillary permeability in shock; this is stagnant or anemic anoxia—all capillaries begin to leak under such conditions.

Secondary shock is due to a loss of blood plasma into the tissues. Hematocrit readings and plasma protein studies show this to be true because there is a great decrease in plasma and an increase in cells. This is perhaps the only way in which shock due to hemorrhage can be differentiated from shock due to loss of blood plasma. However, if bleeding is long continued, enough plasma will be lost to reduce osmotic pressure in the capillaries. They will also become more permeable due to anoxia (caused by the constricted arterioles and reduced volume flow as well as the hemodilution). Capillaries become permeable and fluid is lost in the tissues with resulting edema (Chapter 11). Finally in hemorrhage there may be hemoconcentration. Thus traumatic shock begins with capillary injury, whereas hemorrhagic shock ends this way.

Erythremia in shock may be due in part to splenic contraction. Page and Glasser found that 50 per cent of the increase in red blood cells results from this cause in intestinal manipulation shock and 65 per cent in tourniquet shock. Perhaps the increase in adrenalin during shock may be partly responsible for splenic contraction.

Blood viscosity is increased due to loss of fluid into the injured tissues; this increases the tendency for pooling in the hyporeactive capillaries reducing the circulating blood volume.

By referring to the chapter on hemorrhage we see that the clinical symptoms of shock due to loss of whole blood and shock due to loss of plasma are the same. However, in hemorrhage, when bleeding is controlled symptoms abate and transfusion is curative even after the blood pressure has been as low as 30 mm. Hg for hours. This is not true of traumatic shock in which the capillaries continue to lose plasma twenty-four to forty-eight hours after the injury. Even in severe trauma, where capillaries are actually ruptured, the loss of red blood cells soon ceases due to clotting, but plasma continues to be lost.

Cardiogenic Shock

In cardiogenic shock there is first a cardiac inadequacy and then a fall in arterial blood pressure due to a pooling of the blood. The patient is cyanotic and the veins are distended (especially in the neck). Clinically this type is seen in auricular fibrillation, coronary occlusion, and

resemble traumatic shock, if he is to prevent and treat the syndrome correctly. The chief causes of this type of shock are (1) paradoxic respiratory movement of the thoracic wall with resulting cardiorespiratory incompetence and anoxemia; (2) anoxemia from the accumulation of blood or secretions in the tracheobronchial tree; (3) atelectasis from (2); (4) atelectasis from exhaustion due to labored breathing and frequent ineffective coughing; (5) undue pressure on the lung and mediastinum by (a) the accumulation of large amounts of serum in a wound after rib resections, (b) collapse of the thoracic wall over an intrapleural air or fluid space in which the pressure has not been reduced by aspiration before operation, (c) too great thoracoplastic collapse of the thoracic wall at any one operative stage, (d) too large an intrathoracic packing, (e) too tight a dressing after resection of ribs, (f) abdominal distention; (6) too negative a pressure in the pleural cavity in which the lung cannot expand freely because of stiffness of the visceral pleura.

Crush Syndrome, Ischemic Muscle Necrosis, Traumatic Edema, Traumatic Anuria.—Crush or compression syndrome, ischemic muscle necrosis, traumatic edema, traumatic anuria are terms applied to an injury which results in shock due to burial beneath debris in air raid casualties. This has been discussed in the Historical Review in this chapter. The causes have been listed as toxins, loss of plasma, or autolytic products from dead or dying muscle, injured kidney tubule cells, and precipitation of myohemoglobin in the tubules due in part to renal vasoconstriction with oliguria which favors the intrarenal precipitation of myohemoglobin. The one big factor seems to be a wide area of muscle necrosis due to ischemia, direct compression, or interference with blood supply of the muscles. Early there is a local loss of plasma and fluid; later there is the absorption of a toxic product which produces anuria and uremia. The small quantity of urine which may be excreted contains (if kidney has been torn) some blood pigment which resembles hemoglobin but is, in fact, myohemoglobin, casts, high chloride, high potassium, and creatinine. The blood shows hemoconcentration, high potassium levels, up to twice the normal, and azotemia. Oliguria due to mismatched blood transfusion, oligemic hypotension, wide extravasation of blood into body tissues, and crystal calculi must be differentiated. Hematuria and hemoglobin may be differentiated by examination of the urine—the history is all important.

Blast Concussion.—Injuries may occur due to air or water waves producing shock (see Historical Review). These waves are irregular in outline near the source with eddies in the periphery. Blast waves, like sound waves, are reflected from surface to surface and are subject to reinforcement or neutralization on meeting a similar wave in the same or opposite phase. Pressures vary as the square or cube of the distance from the source. Although there is a negative wave after a blast, this is said to have less influence than the positive wave. In water there is only the positive waves, although if shallow a rebound wave would occur which

magnesium and other substances. The injured area loses potassium and takes on sodium. Thus the blood is low in sodium and higher in potassium. Enough sodium is lost in a traumatized extremity to equal the total amount in the circulating blood and one-fourth that of the total extracellular fluid. Potassium is excreted in the urine in shock. Sodium is not, even after giving it. This means dehydration of the intracellular compartment. Since the blood constitutes only about one-fourth of the sodium reservoir and since the loss is more than the total amount contained in plasma, much sodium must be lost in the tissues (see Chapter 6, Burns, and Chapter 11). Radiation sickness, like high intestinal obstruction, may cause shocklike symptoms due to toxemia or H substances. The protracted symptoms and perhaps the irreversible types of shock may be due to the systemic absorption of toxic substances bacterial in origin produced in crushed muscle, although there is no proof of this recently revived old theory.

In summarizing the present-day knowledge of shock, we must assume that no single factor is responsible. Many of the causes which have been discussed may act at the same time and no doubt all may play an important role in a single case. A common occurrence is to see primary shock from pain followed by secondary shock from blood loss, the patient remaining in shock continuously.

Special Types of Shock

Thoracic.—Following World War I and the advent of major chest surgery, we have learned that in addition to the other causes for shock already mentioned tension pneumothorax presents a special problem. This will be discussed again in Chapter 19. An open wound in the chest (sucking wound) may build up air pressure and in addition fluid pressure if there is bleeding within the thorax and produce profound shock and death due to (1) collapse of the lung on the injured side; (2) reduction of respiratory capacity of the opposite lung from the paradox in respiration transmitted from the injured side (mediastinal flutter), or if there is no flutter there will be a mediastinal shift interfering with respiration of the sound side; (3) reduction of circulatory efficiency by interference with venous return (especially on the right side); also by twisting and shifting the heart induced by the rotary motion of the heart beat; this will also have an effect on the extracardiac autonomics which may not only affect the beat, but the vasomotor mechanism as well (central and peripheral) through aortic and carotid sinus mechanisms. Cardiac tamponade produces shock rapidly. Here a wound of the heart permits the accumulation of blood in the pericardial cavity, restricting cardiac movement.

Obviously surgical shock may occur from thoracic operations from causes already discussed. There is, however, a special type of shock which the thoracic surgeon must recognize, even though the symptoms and signs

the process unless there is, in addition, sunburn. In sunstroke the skin is hot and dry and body temperature may reach 108 to 110° F. The prognosis is grave.

Freezing shock occurs from six to twelve hours after thawing in experimental animals. Extracellular water is decreased, plasma sodium is increased, water enters body cells. In addition, shock may occur from associated factors such as arteriolar relaxation with capillary atony as in tourniquet shock; also thrombosis and embolism (see Chapter 4).

Cold exhaustion. Fatigue and cold produce a desire to sleep. When the body lies motionless in low environmental temperatures, body heat is lost and body temperature falls. At 68° F. coma sets in and death occurs. The fall in temperature depresses the dissociation of oxyhemoglobin and tends to lower oxidation in the tissues (Wright).

COLLATERAL CHANGES IN SHOCK

As a result of deficient blood flow and oxygen supply most organs are temporarily impaired. The *liver* suffers greatly. In shock there is an increased breakdown of protein in the peripheral tissues; this affects chiefly the muscles. There is also a delay in the regeneration of serum protein. Hepatic glycogen decreases and its synthesis from administered glucose is delayed. Metabolic transformation of amino acids is slowed and there is a rise of amino acids in the blood in shocked animals; the rate of urea formation from amino acids is depressed. The loss of potassium from cells may be a toxic factor in shock. Water and potassium are lost from liver cells to extracellular spaces. During recovery there is a tendency for replacement of lost potassium but not complete. Thus we have liver impairment as a result of shock which may tend to perpetuate or at least act as an augmenter of the syndrome. This explains, at least in part, the hypoglycemia, the increase in amino acids, the acidosis, the decrease in serum protein even after capillaries cease their leakage in shock.

The kidneys also are impaired, as indeed are all the cells, from the decrease in blood and oxygen which reaches them. Their particular deficiencies are not entirely known but enough is understood to govern our therapy. The body as a whole and each of its cells are functioning on a minimum supply of food and oxygen. The sooner these requirements are met, the less will be their impairment. Therapy is directed to replace blood, plasma, water, electrolytes, and glucose. It is unreasonable to suppose that the liver can synthesize amino acids into serum proteins during shock or that the kidneys can take out all water and electrolytes not needed. These facts lead the surgeon to selective and judicious treatment in kind and amount. Shock unabated or improperly treated may lead to irreversible changes in cells.

would coincide with the former. As a result of this injury, traumatic lesions are found in the lungs with hemorrhages adjacent to the bronchi, lacerations of the lungs along the line of the ribs, and red hepatization associated with cyanosis, dyspnea, cough, and hemoptysis. Hemorrhages in the intestines and other abdominal organs with pain, distention, absence of peristaltic sounds, and all the symptoms and signs of paralytic ileus may follow immersion blast. Perforation of the intestine is not uncommon and there may even be evisceration. The eyes and ears may also be injured by blast. Shock is profound but usually is accompanied by bradycardia, at least during the early period following injury.

Acceleration Shock.—Acceleration shock is the name given to shock caused by a sudden and extreme change in speed. "G" is the gravitational force on a freely falling body. In aviation acceleration which causes blood to leave the brain is said to be positive and that which causes a sudden rush of blood to the brain, negative. High positive (black out) or negative (redding out) may produce shock. The former is more common and is seen as the plane comes out of a dive. Blood leaves the brain and thorax to enter the large abdominal veins. Since there are no valves in the vena cava and its principal branches (except azygos and spermatic), this is easily accomplished under the terrific force. There follows a drop in carotid and jugular pressures. The centrifugal effect prevents blood from reaching the right atrium. This results in cardiac inadequacy and a fall in blood pressure.

At 5 "G's" the body is beyond control of the muscles except for slight movements of the arms and head. At 7 "G's" there is a failure of filling of the heart. At 20 "G's," which is an acceleration of 640 feet per second, concussion occurs in a fraction of a second. Since the jugular veins have valves, a sudden rush of blood to the brain as the plane descends at a bulletlike speed is unlikely; should it occur the symptoms would include a transitory unconsciousness as in concussion; some attribute this to fat emboli in the finer cerebral blood vessels.

Shock Due to Extremes in Environmental Temperatures.—Shock due to heat has been discussed under "Clinical Causes of Shock. *Overheating* or *heat exhaustion* is due to environmental temperatures above body temperature so that body heat cannot be lost by radiation. If, in addition, there is much moisture in the air, body heat cannot be lost by evaporation. The cerebral heat-regulating mechanism is normal but the body cannot keep its normal temperature because the methods used by the body to lose heat are not effective. The victim goes into peripheral vascular collapse or syncope probably from neurogenic or carotid sinus effects. The oral temperature may be subnormal and the skin is cold and clammy. The prognosis is good.

Sunstroke is due to heat retention caused by a disturbance of the heat regulation centers. The actinic rays of the sun are not involved in

the process unless there is, in addition, sunburn. In sunstroke the skin is hot and dry and body temperature may reach 108 to 110° F. The prognosis is grave.

Freezing shock occurs from six to twelve hours after thawing in experimental animals. Extracellular water is decreased, plasma sodium is increased, water enters body cells. The victim goes into peripheral vascular collapse or syncope probably from neurogenic or carotid sinus effects. The oral temperature may be subnormal and the skin is cold and clammy. The prognosis is good.

Sunstroke is due to heat retention caused by a disturbance of the heat regulation centers. The actinic rays of the sun are not involved in

thirty minutes because its course offers one of the best guides to prognosis and treatment. Yet it has been noted that about 5 per cent of severely injured will show a transient rise in blood pressure for several hours even though other clinical signs are typical for shock. Such patients must be watched closely for they suddenly have a precipitous fall in blood pressure. The reverse is also true in that patients with minor injuries may have a very low blood pressure probably due to vasovagal collapse. A third group in shock may maintain a normal pressure as long as they are recumbent—should they sit or stand the blood pressure falls rapidly.

The pulse is unreliable in the diagnosis of shock although it is usually fast. In vasovagal syncope it is slow and sometimes it may be slow in severe hemorrhagic shock. More often it is fast due to fear or excitement out of all proportion to the loss of blood volume. As a rule, however, the pulse varies inversely with the blood pressure and is useful in prognosis and diagnosis in relation to the pressure.

The skin is very unreliable in the diagnosis of shock yet as a rule it is pale, cold, and clammy. A few simple experiments will illustrate the variations in skin color. If a blood pressure cuff is placed on the arm of a normal individual, held at the level of the heart, and is inflated above systolic pressure the arm becomes pale and ashen, and the nail beds become cyanotic. This resembles shock without blood loss. Arterial color replaces the cyanosis on release of the cuff, indicating a good circulation. If now the same test is repeated with the arm held high above the head before the cuff is applied, there will be extreme pallor with only a little cyanosis in the nail bed. This resembles the color of the skin in hemorrhagic shock and shows the greatest diminution of blood in the skin. Lastly, if the same experiment is tried with the arm hanging down, there is a bright red-purple color and finally deep cyanosis—the counter part of shock from massive infection.

The clinical symptoms and signs of shock are generally as depicted; however, variations do occur and it is the combination of symptoms and signs which leads to accurate diagnosis.

Laboratory Aids in Diagnosis of Shock.—Hemoconcentration is probably the most frequently used single factor for the recognition of shock.

A hematocrit reading reveals a low plasma-high cell ratio. The red blood cell count will be high. A rise from 5 to 6 million cells represents a concentration of 20 per cent. This, according to Moon, indicates that the total blood volume has been reduced about 10 per cent and the plasma volume, 20 per cent. Hemoconcentration of 40 per cent (count of 7 million) is always accompanied by all of the clinical symptoms and signs of shock. The specific gravity of the blood roughly parallels the hematocrit readings: that is, it will be increased in hemoconcentration. Hemoglobin readings will rise with the increase in cells.

IRREVERSIBLE SHOCK

The term irreversible shock is used to denote the syndrome with peripheral vascular failure which does not respond to remedial measures. Since in most instances the principal cause is a decrease in circulating blood volume, in the irreversible phase life cannot be sustained even if the blood volume is restored completely.

Clinically irreversible shock is seen in severe infections, lesions involving the central nervous system, anoxic anoxemia due to pulmonary damage, and a long-persisting combination of anemia, oligemia, and hypotension with terminal signs of myocardial insufficiency.

We have noted that hypotension due to hemorrhage is better borne than that due to extensive capillary damage, although ultimately in either event, stagnant or anemic anoxia causes all capillaries to leak, and plasma or fluid introduced under pressure will be lost in the pleural, peritoneal, pericardial, and meningeal spaces later in the subcutaneous tissues. There is also a failure of cellular metabolism in irreversible shock. In fact, many organs, especially the brain and heart, resist anoxia less than the capillaries. This is borne out by the fact that there is a depression of respiration and damage to heart cells before capillaries begin to leak especially in shock due to generalized infection; this is due to the destruction of cells by interference with the enzyme systems. *Irreversible shock then is due to the permanent damage of heart cells, brain cells, and capillary endothelium from prolonged circulatory failure.*

DIAGNOSIS OF SHOCK

Shock is easily diagnosed by the symptoms and signs previously enumerated. The particular type of shock may be ascertained by a brief history of the injury or disease and by laboratory aids. No single symptom or sign or laboratory finding is diagnostic. Even the knowledge of the exact amount of blood lost will not permit the prediction of shock. The average adult will tolerate the acute loss of one liter of blood without shock except the vasovagal type of collapse. Profound shock with systolic blood pressure of 60 mm. Hg or less usually means a loss of 2 liters of blood. Yet profound shock may occur from the loss of less than 1 liter.

People who are injured may have pre-existing conditions which enter into the picture such as dehydration, microcytic anemia, cardiac failure, etc. Moreover, there is no way of predicting how far the compensatory mechanisms will go in preventing shock. Lastly, irreversible shock may often be anticipated but should not be invoked as a deterrent for active treatment.

Let us consider (a) the usual clinical symptoms and signs, (b) variations, (c) laboratory data, and (d) modifications.

The most reliable clinical means of diagnosing shock is a persistent fall in arterial pressure. In suspected shock this should be taken every

(7) Differences in capillary and venous plasma protein and hematocrit values—blood proteins sometimes show a slight difference in values taken from capillary and venous blood—the former may be slightly higher because it is diluted less with intercellular tissue fluid. Thus there may be a higher protein and a higher hematocrit in capillary blood than in venous blood, the higher protein due to loss of water first and plasma later, the higher hematocrit due to loss of water earlier with less dilution than in veins. Other blood changes include a decrease in platelets in *shock and an increase in potassium and a decrease in sodium.*

Laboratory aids are very useful in the diagnosis and treatment of shock. With the copper sulfate method the hematocrit and plasma protein values may be obtained quickly and accurately. Blood counts and hemoglobin determination are also easy to obtain and aid in evaluating the necessity for plasma, whole blood, or water. The quantity and specific gravity of the urine is an indication not only of the water balance (q.v.) but also of the osmotic index of the blood. However, finally one must consider all laboratory tests in the light of clinical symptoms and signs which, after all, constitute the only real method of diagnosis.

Surgical Shock

A surgical operation is an experiment in which the knowledge and skill of the physician is pitted against the ravages of disease. It is the surgeon's duty to evaluate the patient's ability to stand surgery and to *prepare* him for the ordeal. He must be meticulous in the conduct of his operation and then meet the requirements necessary to assure recovery after the operation has been completed.

Preparation for Surgery (Preoperative Care).—In the list of aphorisms (Chapter 1) we have seen that, "There is no operation that has merit enough to be used on a patient who cannot stand it." To put the patient in good condition we must determine how he varies from the normal due to (a) the disease, (b) his deficiencies caused by the disease, and (c) complications. Thus if the patient is normal he needs no preparation except to combat fear and to secure rest before the operation by the use of sedatives. If he is deficient, much treatment may be necessary before surgery can be safely done. Although every need of the patient cannot be discussed here, it is important to emphasize that attention to details may prevent a chain of events leading to shock. What normal requirements must be fully met if the shock is to be prevented?

1. *Oxygen-Anoxemia.*—Anoxemia from any cause must be combated (anoxic, anemic, stagnant, histotoxic, or combinations). Eliminate cause if possible and give oxygen.

2. *Blood.*—Quantitative or qualitative deficiencies may be due to disease of blood-forming organs, excessive loss of blood, or a disproportion between the volume of circulating blood and the vascular bed. Give

Hemorrhage may be differentiated from shock by these studies, for the blood will be diluted within two hours or more after bleeding occurs. Blood counts and hemoglobin will be low. In shock due to hemorrhage hemoconcentration may be present, but to a lesser degree and very late. However, if hemorrhage is due to capillary trauma (extensive injuries by blunt force) hemoconcentration gradually develops and equals that seen in burns, trauma to the intestines, intestinal obstruction, or other types of shock.

Based upon this observation, Phillips, Van Slyke, and associates have described the copper sulfate method for measuring specific gravities of *whole blood and splasma. Their line charts for calculating plasma proteins, hemoglobin, and hematocrit from plasma and whole blood gravities offer a quick method of obtaining accurate information in a* very few minutes.

Since hemoconcentration is not a regular feature of shock except in burns and crushing injuries, it *must be interpreted as one of* the symptoms in diagnosis and as a guide to treatment. Indeed experiments show that hemoconcentration per se does not cause shock—it is the reduced blood volume and anoxia.

Plasma proteins are low when plasma has been lost, high in hemoconcentration due to water loss, and low after hemodilution in hemorrhage. Blood volume is reduced and the extent of this reduction may be ascertained by the use of Evan's blue dye as described in Chapter 13, albeit this is still an unhandy procedure.

Hematocrit, plasma proteins, and chlorides may be normal yet total volume so low that life cannot be sustained. Many factors may contribute to this incongruity: (1) *Lack of hemodilution—after hemorrhage and before the fluid shift from intercellular tissue spaces has occurred,* the various constituents, though *reduced* in total quantity, appear to be relatively normal because there has been no hemodilution; studies of the total volume by Evans blue T-1842, as described in Chapter 13, will disclose the amount of blood lost. (2) Pre-existing microcytic anemia—in microcytic anemia a normal hematocrit may mean hemoconcentration. (3) Pre-existing polycythemia vera—in polycythemia vera, on the other hand, a *high* hematocrit may mean a normal ratio for that individual. (4) *Increased volume of the red cells after hemorrhage—one to two days* after hemorrhage *due to the low osmotic pressure* red blood cells may swell and take more volume than they should. (5) Dehydration—in dehydration even though plasma and cells have been lost, hematocrit may be normal. (6) Differences in capillary and venous blood counts—in wound shock red blood counts from the finger tip (capillary blood) may be 2 to 3 *million* higher than from venous blood. Presumably a similar difference of *30 to* 40 per cent occurs in the *hemoglobin. This is probably due to the fact* that the *peripheral "tourniquet" has been put on*—arteriolar constriction with *capillary* stasis and therefore increased hemoconcentration.

6. *Environment.*—The patient should be kept at about room temperature—70° F.—warm not hot.

7. *Asepsis.*—Strict asepsis should be observed.

8. *Blockage of Afferent Nerve Impulses.*—There is no proof that blockage of afferent nerve impulses through the use of local or spinal anesthesia prevents shock.

After the Operation.—How has the surgical procedure interfered with the normal body requirements? If not at all, relieve pain which may cause shock and nothing more. Excessive and unnecessary treatment is a burden on the patient and may have serious consequences (see Chapter 13).

Common interferences are:

1. *Oxygen Consumption.*—After open chest operations there may be anoxic anoxemia. However, all types of anoxemia may occur and demand correction. The following measures may be helpful: oxygen inhalation, aspiration of the trachea and bronchi by catheter suction or bronchoscopy, deep breathing, adequate negative pressure on the operated side (see Chapter 19), and blood transfusions as needed.

2. *Loss of Blood and Fluid.*—Loss of blood and fluid inadequately replaced during surgery or being lost afterward due to drainage or postoperative hemorrhage demands transfusion and infusions of water and electrolytes—avoid dehydration.

3. *Inability to Take Fluid or Food or Assimilate It.*—This must be provided by the use of plasma, protein hydrolysates, glucose, and sodium chloride and vitamins.

4. *Elimination.*—Elimination must be maintained by catheter drainage, intestinal suction, or enterostomy, free breathing, clean skin; avoid azotemia, toxemia, acidosis, and alkalosis.

5. *Contamination.*—Contamination may lead to infection. Antibiotics and chemotherapeutic agents should be given by mouth or parenterally.

6. *Early Mobilization.*—Early mobilization to avoid thrombosis and embolism.

7. *Environment.*—The patient should be kept warm not hot.

8. *Complications.*—Watch for the complications which cause shock. One of the best methods to discover shock early is to check the blood pressure and pulse every hour for the first twenty-four hours.

THE TREATMENT OF SHOCK

The studies which have been described have a very practical application in prevention and treatment. *In civilian life shock is encountered* most commonly from extensive wounds, burns, or fractures and after surgical operations. There is no way of preventing shock in the former; however, much can be accomplished in the way of prophylaxis in the latter.

whole blood or plasma or blood cells as required. Have enough blood on hand at all times to keep blood volume as nearly normal as possible. Use vitamin K.

3. *Water and Electrolytes and Food.*—Enough water must be given to meet ordinary needs but not too much. If there has been vomiting or diarrhea, enormous quantities may be needed. The ability to eat, drink, and assimilate food portends normal function. The alimentary canal and not the veins was made for those functions. In disease states normal channels may not be usable and the intravenous or subcutaneous routes must be employed; starvation states must be corrected before surgery (see Chapter 12). Vitamins must be supplied.

4. *Elimination.*—The ability to eliminate waste products, acid or base, is necessary for the avoidance of azotemia, toxemia, acidosis, and alkalosis. Therefore, interference with kidney or bowel function should be corrected if possible. Anuria may be avoided by attention to water, electrolyte, and colloid requirements if prerenal, or by drainage if postrenal. Bowel impairment due to obstruction may be relieved by tube suction or enterostomy.

5. *Ability to Withstand Infection.*—Chemotherapeutic agents and antibiotics make the environment unfavorable for bacterial growth.

During the Operation.—The most common causes for shock during surgery must be constantly borne in mind and avoided.

1. *Oxygen.*—Shock due to anesthetic agents is not common. It is usually anoxic anoxemia. This is avoided by a clear airway and liberal amounts of oxygen. Prolonged, deep anesthesia may cause shock during and after the operation—the former by affecting the respiratory and cardiac centers, the latter by prolonged lack of motion with pooling of blood.

2. *Blood.*—The surgeon must know the approximate amount of blood loss (see Chapter 14). He must avoid undue loss of blood by using accurate hemostasis, and he must replace that which he loses by transfusion during surgery. Therefore in all operations which ordinarily are accompanied by considerable blood loss, transfusions are started immediately after the operation begins. This is routine.

3. *Fluid and Electrolytes.*—Fluid and electrolytes are also replaced during surgery.

4. *Handling.*—Prolonged handling, roughness to gain time, prolonged exposure, even if tissues are handled gently, invite shock. Long procedures are better done in stages if this is feasible.

5. *Positions.*—The extreme Trendelenberg position and quick changes back to the horizontal after it has been employed may cause shock due to interference with the proper breathing and overloading the right heart while in the head-down position, and due to suddenly pooling blood in the abdomen when the horizontal position has been resumed.

6. *Environment.*—The patient should be kept at about room temperature—70° F.—warm not hot.

7. *Asepsis.*—Strict asepsis should be observed.

8. *Blockage of Afferent Nerve Impulses.*—There is no proof that blockage of afferent nerve impulses through the use of local or spinal anesthesia prevents shock.

After the Operation.—How has the surgical procedure interfered *with the normal body requirements? If not at all, relieve pain which may cause shock and nothing more. Excessive and unnecessary treat*ment is a burden on the patient and may have serious consequences (see Chapter 13).

Common interferences are:

1. *Oxygen Consumption.*—After open chest operations there may be anoxic anoxemia. However, all types of anoxemia may occur and demand correction. The following measures may be helpful: oxygen inhalation, aspiration of the trachea and bronchi by catheter suction or bronchoscopy, deep breathing, adequate negative pressure on the operated side (see Chapter 19), and blood transfusions as needed.

2. *Loss of Blood and Fluid.*—Loss of blood and fluid inadequately replaced during surgery or being lost afterward due to drainage or postoperative hemorrhage demands transfusion and infusions of water and electrolytes—avoid dehydration.

3. *Inability to Take Fluid or Food or Assimilate It.*—This must be provided by the use of plasma, protein hydrolysates, glucose, and sodium chloride and vitamins.

4. *Elimination.*—Elimination must be maintained by catheter drainage, intestinal suction, or enterostomy, free breathing, clean skin; avoid azotemia, toxemia, acidosis, and alkalosis.

5. *Contamination.*—Contamination may lead to infection. Antibiotics and chemotherapeutic agents should be given by mouth or parenterally.

6. *Early Mobilization.*—Early mobilization to avoid thrombosis and embolism.

7. *Environment.*—The patient should be kept warm not hot.

8. *Complications.*—Watch for the complications which cause shock. One of the best methods to discover shock early is to check the blood pressure and pulse every hour for the first twenty-four hours.

THE TREATMENT OF SHOCK

The studies which have been described have a very practical application in prevention and treatment. In civilian life shock is encountered most commonly from extensive wounds, burns, or fractures and after surgical operations. There is no way of preventing shock in the former; however, much can be accomplished *in the way of prophylaxis in the* latter.

Once shock has occurred, an attempt should be made to diagnose its cause. Often this is very difficult, sometimes impossible. If we are able to diagnose the type of shock, this is of great value. Is it hematoggenous? If so, there is blood loss somewhere and this must be controlled. A brief reference to the causes of shock, as herein enumerated, will reveal immediately the complexity of the problem. However, if the different causes are kept in mind and if the patient is examined carefully, a diagnosis usually may be made.

While we are attempting to solve our problem as to cause, we must not neglect our patient lest he slip beyond our reach. One must not be so greatly concerned over the possible cause that he focuses his entire attention upon it and forgets that the patient is dying of shock. For in spite of the lack of diagnosis, the patient must be given adequate general treatment or he may succumb before the cause is found.

The Treatment of Neurogenic Shock

Since this type of shock is due to a pooling of blood, chiefly in the splanchnic area, the head down or at least a flat position is indicated. Tight clothing should be loosened; modest stimulation may be obtained by cold water to the face or the inhalation of aromatic spirits of ammonia. Carotid sinus syncope is helped by the foregoing measures and in addition atropine sulfate given hypodermically is indicated.

The Treatment of Traumatic Shock

In Chapter 13 we discussed the treatment of shock due to hemorrhage. Traumatic injuries include loss of whole blood, but in addition many other factors must be considered. Life cannot exist very long without oxygen or blood. Therefore our very *first consideration* in the management of severe injuries is to combat anoxia from whatever cause (see Chapter 19) and, no less important, to *control hemorrhage* or *the loss of plasma*. Every drop of blood counts. The same may be said of plasma. We have noted the effects of tourniquets on mangled extremities. Although they are often necessary, the rules for their use should be carefully followed (see Chapter 13). A tight pressure bandage is best until the bleeding vessel or vessels may be ligated or at least clamped. The use of cold to freeze a mangled extremity has been advocated because (1) it permits the use of a tourniquet for long periods due to the fact that it allows living tissue to survive on a low margin of blood supply; (2) it decreases the rate of autolysis; (3) it decreases the absorption of toxins (see Chapter 4). This is useful only if the extremity is to be amputated because such freezing not followed by amputation leads to gangrene or death from shock, infection, or both. If concealed bleeding is present, resuscitative measures must be instituted and the site of hemorrhage sought at the same time (Chapter 13). In burns plasma is held in the capillaries by external pressure or subcutaneous saline solution (see Chapter 4).

Rest.—The patient as well as his injured extremities must be put at *rest*. No matter what the cause of the injury, rest decreases pain and lessens exudation. For this reason temporary splints are important even though the trip to the hospital is a short one. Rest for the patient implies physical and mental rest. He should be kept quiet—for this purpose morphine may be necessary to relieve pain; a darkened, noiseless room to avoid any stimulation (shock room); and reassurance when consciousness occurs. Morphine is important but may increase anoxia by depression of the respiratory center. Therefore it should be used cautiously. This is especially true since it is usually given intravenously in shock. Drugs are not readily absorbed when given hypodermically, due to the peripheral vasoconstriction; consequently ¼, ½, ¾ Gm. may be given with little effect. As soon as blood volume has been partially restored, all of this will be absorbed at once, producing great respiratory depression even causing death. The "head down" position advocated by many is used with the idea that venous return to the heart will be facilitated. While this may be true, its disadvantages outweigh its advantages and therefore should not be used. This is clear enough in shock due to head injuries where blood should be pooled in the abdomen and in thoracic injuries where respiratory embarrassment may be increased. However, it is equally true that in abdominal injuries the diaphragm may be impeded by intra-abdominal bleeding or intestinal content or gas. At best this position leads to impaired breathing unless the air passage is clear so that an airway tube must be used in the unconscious patient, for any difficulty in respiration with a full right heart may lead to right-sided failure. Therefore the horizontal position is used except in shock due to head injuries or chest injuries, for which slight head elevation is indicated.

Restoration of Blood Volume.—Some fundamental axioms in restoring blood volume are (1) give that which has been lost; (2) take into account hydrostatic and osmotic pressures as well as the condition of capillary walls; (3) give fluid by mouth if possible; if not, use the intravenous route except with physiological saline which may be given subcutaneously with safety; (4) clinical symptoms and signs are the best guides as to adequacy of treatment.

In Chapters 12 and 13 we have discussed the various types of crystalloid and colloid solutions which are available for the restoration of blood volume, intercellular and intracellular water and electrolyte content. It should be borne in mind that (1) body fluids in blood and in interstitial and intracellular compartments form an isosmotic system in which semipermeable membranes maintain the solid content of the three phases with water transfer maintaining an equilibrium and a uniform osmotic pressure in all; (2) plasma is the most important part of the blood as regards its osmotic pressure because capillaries are normally relatively impermeable to the proteins it contains.

An enormous volume of literature has been written on the merits and demerits of the various solutions available in the treatment of shock. They fall into the following groups:

1. *Isotonic and Hypertonic Solutions.*—In the preceding paragraph we have noted that the fluid compartments are isosmotic. The great danger of hypertonic or concentrated solutions in patients who are in shock is that of dehydration, not only interstitial but intracellular as well. Also there is a direct stimulation of arterioles with more pooling in capillaries, although a transient rise in blood pressure occurs. Then, too, hypertonic solutions may cause kidney damage (see Chapter 12) and injury to vessel walls. Since a patient in shock may or may not have ample interstitial water, concentrated solutions are not as safe as isotonic solutions.

2. *Colloid and Crystalloids.*—Both are needed in shock. It is the sodium and potassium ions that are important, not only for osmotic reasons but also because sodium is lost into injured tissues where it may help neutralize toxins due to trauma. At any rate it must be replaced. Amounts equivalent to about 5 per cent of the body weight may be given parenterally during the first twenty-four hours. Saline cannot replace plasma but must be used with it because normally capillaries are permeable to crystalloids. If large volumes of saline are introduced, hydrostatic pressure is increased within the capillaries and osmotic pressure is reduced due to dilution; therefore, more fluid and plasma will be lost, thereby further reducing osmotic pressure. Those who favor saline over plasma aver that the loss of protein is due to local tissue breakdown, that plasma dilutes electrolytes which are vital, that glucose or plasma may stimulate metabolism, causing an increased tissue demand for oxygen. The latter is not true since protein and glucose are not synthesized during shock.

3. *Colloid Substitutes for Plasma.*—Gelatin, isinglass, pectin, methylcellulose, polyvinyl alcohol, vinyl pyrrolidon polymer—hydrophillic colloids, cause conglomeration and increased sedimentation of erythrocytes. Moreover, they do not furnish any material for the restoration of lost plasma protein and they may interfere with the formation of such proteins; they also may cause severe anemia due in part to their retention in the internal organs, especially the liver. Such inert materials should not be used when plasma is available.

4. *Amino Acids or Plasma Proteins.*—In Chapter 11 we discussed the use of protein solutions which are obtained from casein and pork pancreas or from casein alone as a source for amino acids. Such solutions used in concentrations of 5-10 per cent may be valuable when the liver is able to synthesize them into plasma proteins. In shock the liver does not function fully and therefore such synthesis is not available. Even if it were, the time element would preclude its use for an immediate source of plasma protein. Therefore plasma is much preferable.

5. *Whole blood, or Suspension of Red Blood Cells or Plasma or Albumin.*—These are the most needed and desirable remedies for shock.

Whole blood is always valuable in shock. This is true in cases where most of the blood volume loss is due to plasma. We have noted that in the treatment of burns, whole blood is useful even though there is hemoconcentration (see Chapter 6). The circulating hemoglobin may be rapidly reduced to one-fourth of the normal level with few symptoms, but a loss of approximately one-half the total blood volume is usually fatal. A million red blood cells per cubic millimeter can maintain life provided the circulating fluid volume is normal or nearly so. This is evident by the many patients who are brought into the hospital with erythrocyte counts of a million or even less. Of course the blood has been depleted slowly. Therefore it is fluid volume that is of immediate importance, although red blood cells are necessary to carry oxygen and anoxemia is one of the prime causes of shock. If there has been great blood loss or if there is a low hematocrit or *air hunger* (Chapter 19), whole blood is preferable. In the latter connection it is well to remember that cyanosis may be absent due to the fact that there is less than 5 Gm. of reduced hemoglobin in the circulation. Such patients will not be relieved by oxygen inhalation. They must have red blood cells.

Plasma will control shock even though it is due to hemorrhage because it will provide a medium to carry corpuscles, thereby decreasing anoxia; it may serve to mobilize red blood corpuscles sequestered in the various storehouses of the body such as the spleen and bone marrow and smaller vessels and actually lead to an increase in the blood count. Plasma is not a substitute for red blood cells, but it will tide over the critical patient and the erythrocytes will come later or may be given as *red blood cell suspension* in isotonic saline. The great value of plasma is that it is immediately available without typing and it fulfills all of the requirements for the maintenance of a blood volume compatible with life and physiological requirements (Chapters 11 and 13).

Serum albumin is, as we have noted in Chapter 11, the most important protein in plasma in the maintenance of osmotic pressure. Each gram of albumin should hold the equivalent of 18 c.c. of fluid in the circulation and a 5.6 per cent albumin solution should be isotonic with a 7 per cent plasma. Thus 25 Gm. of albumin is osmotically equivalent to 450 c.c. of circulating plasma or 500 c.c. of citrated plasma. During World War II a 25 Gm. package was available. Human serum albumin is very useful but difficult to obtain. It may be repeated at fifteen- to twenty-minute intervals, but when used in this concentrated form it is objectionable for reasons already given in the discussion of hypertonic solutions.

6. *Large or Small Transfusions.*—In hemorrhage where large amounts of blood have been lost a large quantity of blood must be replaced. This is particularly true during an operation where vessels may be ligated or

bleeding controlled by pressure. Where spontaneous arrest of hemorrhage is depended on, several small transfusions are preferable to one large one because of the sudden increase in blood pressure. This may actually precipitate further bleeding (Chapter 23). Shock due to trauma is also best treated by repeated small (500 c.c.) transfusions. This permits for vascular and other adjustments and precludes the possibility of shock from too much volume (plethora) with pulmonary edema or cardiac failure from overdilation. In addition, excessive amounts of whole blood lead to other serious complications such as intravascular thrombosis, stagnant anoxemia, anuria, and citrate poisoning which may lead to a fatality. Later complications include cerebral vascular accidents due to thrombosis or petechial hemorrhages and severe jaundice.

Use of Oxygen in Shock.—Oxygen is a subsidiary form of treatment in shock and when available it should be used. It is especially indicated in chest and head injuries. Oxygen is most effective when given under pressure. In anoxia free oxygen in the plasma must get to the cell which suffers not so much from lack of oxygen as from lowered tension (see Chapter 19).

Use of Heat or Cold.—Recently much has been written concerning the use of cold in almost all human ailments. In our *Synopsis of Principles of Surgery* we stated: "Keep the patient *warm*—surround him with hot water bottles and blankets." Notice we did not say keep the patient *hot*. In the beginning of this chapter we noted that peripheral vasoconstriction was necessary so that the vital centers could have a sufficient amount of blood and that perspiration is augmented so that body temperature may be lowered through evaporation, thereby reducing metabolism and the demand for oxygen in the presence of anoxemia. These we said were compensatory mechanisms. It is therefore wrong to cause peripheral vasodilation with external heat, defeating the provisions of nature's mechanisms, and moreover patients may be burned. Experimentally shocked animals live longer in cold than in heat and shock in very high environmental temperatures is more apt to be fatal than shock in cold, not freezing, temperatures. High temperatures decrease chance for life and shorten survival time in experimental animals, whereas cold lengthens survival time but does not increase the chance to survive. The fall in metabolism amounts to about 13 per cent for each degree centigrade that the body temperature is reduced. Subnormal temperature tends to prevent relative anoxia by diminishing the speed with which oxygen is used. The fall in temperature, as we have seen, is not the result of anoxia but is a protective mechanism, although anoxia does cause a fall in body temperature. A patient going into shock may feel warm; this is the converse of the chill which makes him feel cold. The former is a method for lowering body temperature, the latter for increasing it. The feeling of warmth like the sweat after a chill is to lower body temperature.

Those who are opposed to the use of cold in the treatment of shock aver that relatively little blood can be expressed from the skin because of peripheral vasoconstriction and that cooling of the body surface attended by a fall in body temperature of as little as 0.5 degree may induce shivering which would greatly increase the expenditure of energy and increase the blood flow through skeletal muscles. Furthermore, as the temperature of the body is reduced, hemoglobin holds oxygen more firmly, thereby aggravating the anoxemia that is present in shock.

Recent studies of recorded times of immersion of shipwreck survivors show that tolerance to water at temperatures below 68° F. is limited by the loss of body heat at a rate which exceeds heat production. Heat loss in water is twice that in air. In water, once the rectal temperature falls below 95° F., heat production decreases, respiratory and circulatory irregularities appear, and death ensues.

Lastly, if peripheral blood is cooled too rapidly, a slower circulation with increased stagnant anoxemia results. They believe that external heat as supplied by hot-water bottles and blankets cannot cause vasodilation and that if fluids are being administered it keeps the revived patient comfortable and is therefore useful.

It is undoubtedly true that extreme heat is harmful and that, in general, elevations of environmental temperatures cause more disastrous results than cold. A patient in shock is treated best by keeping him in an environment of 80 to 85° F., in other words, warm. It is indeed a far cry from extreme heat to allowing a patient struck by an automobile on a cold day to lie uncovered because he might force some blood to the surface. Hot-water bottles and blankets to keep him warm and dry is still good supplementary treatment for shock.

The Use of Drugs.—

Hypodermic injections of drugs are not readily absorbed due to the decrease in the circulating blood, to stasis, and to the flow of fluid and plasma into the tissues. Therefore, drugs are usually given intravenously. Caffeine sodium benzoate has been advocated and is useful for it increases blood flow and may improve stagnant anoxia. Adrenalin, ephedrine, and Tuamine sulfate have been advocated by some and condemned by others. Certainly the arterioles are constricted as much as possible in shock. More constriction or elevation of arterial pressure which does occur transiently simply causes more plasma to flow out of the dilated permeable capillaries, causing a prolonged lowering of blood pressure. In fact, a slow infusion of adrenalin may cause shocklike states to occur. Clinical experience bears out the logic of this contention. Even in the critical stage, where vasodilatation is present, adrenalin acts in a fleeting manner and although it temporarily causes an elevation of blood pressure (due to a temporary improvement of the coronary circulation and arteriolar vasoconstriction), this is followed by a more pronounced and prolonged fall in blood pressure. Vasoconstrictor

drugs like adrenalin are useful in shock due to (1) spinal anesthesia, (2) spinal trauma, (3) anaphylaxis, and (4) histamine. In the first two it acts upon the dilated arterioles; in anaphylaxis its action is not definitely known but bronchiolar spasm is lessened. In histamine shock the arterioles are dilated. Adrenocortical hormone (eschatin) does not prevent shock when used preoperatively but is said to decrease capillary permeability in shock. Experimental and clinical experience indicates that plasma is not better retained with than without it. (See Chapter 22.)

Attend to the injury which has brought on the shock after resuscitation is complete; that is, if a mangled leg is the cause, it may now be treated in accordance with sound surgical principles.

Surgical operations should not be done with a patient in profound shock. In all injuries external bleeding is controlled first; then measures are taken to replace blood volume. Internal injuries are divided into two classes: those associated with great blood loss and those without. In the former large quantities of blood are given and operation is done as indicated, as soon as there is fair reaction. Blood is given during and after the operation as well. In ruptured ectopic pregnancy with hemorrhage, or bleeding duodenal ulcer (despite recent advice to the contrary), if resuscitation cannot be obtained, at least partially, an operation should not be attempted. Natural arrest of bleeding will occur in most cases, and after reaction is complete surgery may be done much more safely. In ruptured viscera without massive hemorrhage, reaction from shock is obtained before surgery. This is usually accomplished within 1 to 2 hours.

The Treatment of Cardiogenic Shock

The surgeon may see this form of shock during an operation. Manual massage through the diaphragm may result in a return of regular cardiac contraction. This occurred during an operation by the author for carcinoma of the lower esophagus. Resection was complete when suddenly the heart stopped. Cardiac massage was carried out for two minutes before feeble contractions were resumed; 1,000 c.c. of whole blood were given during the procedure and 500 c.c. more were started. Fifty milligrams of procaine hydrochloride were injected into the left ventricular cavity. This was repeated in two minutes. After this the contractions were normal. The patient recovered and is still well four years later. Some recommend the injection of adrenalin directly into the heart muscle, 1 c.c. of a 1:1000 solution. (See Chapter 17.) For coronary thrombosis the relief of pain is paramount. The best drugs are morphine, 0.015 Gm. (1/4 grain) intravenously, or 100 mg. of Demerol, hydrochloride, or papaverine, 0.03 to 0.1 Gm., intravenously. Complete rest and oxygen by inhalation are important adjuncts to treatment. Fluid balance must be maintained, and for this purpose isotonic saline by hypodermoclysis is best.

This route is chosen because it supports the distended veins by increasing *intercellular space pressure and it will be absorbed more slowly, thereby* avoiding an overload on the heart. (See Chapter 11.)

The Treatment of Toxemic Shock

We have seen that extensive burns produce shock. The same effect is noted when inflammations of the skin arise from other causes such as severe dermatitis, cellulitis, gas gangrene, etc. Since the peritoneum is equal to the skin surface, inflammations involving a large part of the peritoneum are also likely to cause shock. The toxemia is partly bacterial but also may be due to other factors as discussed in Chapter 6 under Burns, in this chapter under Traumatic Shock, and in Chapter 4 under Diffuse Inflammations.

The treament is the same as that for traumatic shock with a few additions and modifications. Fresh blood or fresh plasma is desirable because *of its high antibody titer. Antibiotics and chemotherapeutic* agents are necessary. In tetanus and diphtheria antitoxin is indicated.

Treatment in Special Types of Shock

Thoracic.—Shock may occur following thoracic injuries or operations just as in other parts, and its prevention and treatment has been described. There is, however, a type of shock which resembles ordinary shock but which is peculiar to chest operations and injuries. The chief causes of this type of shock have been discussed. The treatment will be discussed again in Chapter 19. A brief summary is included here.

A "sucking" wound of the chest must be plugged immediately, using petrolatum gauze, dry gauze with adhesive, the hand, or anything which is available. In the hospital it will be sutured. Tension pneumothorax is relieved by inserting an aspirating needle in the second or third *intercostal space anteriorly in the nipple line. Air will escape* under pressure. If this continues a slit finger cot, or the finger of a rubber glove slit at the end may be tied to the hub of the needle which is anchored to the chest wall by adhesive. In this way air can get out but not in. Or a tube may be attached to the needle and placed under water, permitting the exit of air or fluid but *not its entrance.*

Postoperative shock following thoracic operations (see Chapter 19) is treated by replacing blood volume and giving oxygen by inhalation. Parodoxic respiratory movement is prevented by not removing too many ribs at one time in thoracoplasty. It is treated by placing a firm pressure *dressing over the area of paradoxic* movement, an inflated rubber vest, allowing the patient to lie on the area, aiding him to evacuate retained pulmonary secretions (q.v.) so that dyspnea will be reduced and therefore the paradoxical movement lessened; in severe cases the Drinker respirator may be used. Air and fluid must be aspirated from the pleural cavity *if it accumulates under tension.* To prevent this, air-tight closure

drugs like adrenalin are useful in shock due to (1) spinal anesthesia, (2) spinal trauma, (3) anaphylaxis, and (4) histamine. In the first two it acts upon the dilated arterioles; in anaphylaxis its action is not definitely known but bronchiolar spasm is lessened. In histamine shock the arterioles are dilated. Adrenocortical hormone (eschatin) does not prevent shock when used preoperatively but is said to decrease capillary permeability in shock. Experimental and clinical experience indicates that plasma is not better retained with than without it. (See Chapter 22.)

Attend to the injury which has brought on the shock after resuscitation is complete; that is, if a mangled leg is the cause, it may now be treated in accordance with sound surgical principles.

Surgical operations should not be done with a patient in profound shock. In all injuries external bleeding is controlled first; then measures are taken to replace blood volume. Internal injuries are divided into two classes: those associated with great blood loss and those without. In the former large quantities of blood are given and operation is done as indicated, as soon as there is fair reaction. Blood is given during and after the operation as well. In ruptured ectopic pregnancy with hemorrhage, or bleeding duodenal ulcer (despite recent advice to the contrary), if resuscitation cannot be obtained, at least partially, an operation should not be attempted. Natural arrest of bleeding will occur in most cases, and after reaction is complete surgery may be done much more safely. In ruptured viscera without massive hemorrhage, reaction from shock is obtained before surgery. This is usually accomplished within 1 to 2 hours.

The Treatment of Cardiogenic Shock

The surgeon may see this form of shock during an operation. Manual massage through the diaphragm may result in a return of regular cardiac contraction. This occurred during an operation by the author for carcinoma of the lower esophagus. Resection was complete when suddenly the heart stopped. Cardiac massage was carried out for two minutes before feeble contractions were resumed; 1,000 c.c. of whole blood were given during the procedure and 500 c.c. more were started. Fifty milligrams of procaine hydrochloride were injected into the left ventricular cavity. This was repeated in two minutes. After this the contractions were normal. The patient recovered and is still well four years later. Some recommend the injection of adrenalin directly into the heart muscle, 1 c.c. of a 1:1000 solution. (See Chapter 17.) For coronary thrombosis the relief of pain is paramount. The best drugs are morphine, 0.015 Gm. ($\frac{1}{4}$ grain) intravenously, or 100 mg. of Demerol, hydrochloride, or papaverine, 0.05 to 0.1 Gm., intravenously. Complete rest and oxygen by inhalation are important adjuncts to treatment. Fluid balance must be maintained, and for this purpose isotonic saline by hypodermoclysis is best.

Blast Concussion and Immersion Blast.—The treatment of blast concussion is first that of traumatic shock; then it is largely governed by individual indications. Usually it is symptomatic. If extensive hemorrhage or laceration of solid or hollow viscera is evident, surgery is necessary.

Acceleration shock rarely occurs from accelerations in the transverse axis of the body. With positive acceleration if blood could be kept from leaving the head and chest, ill effects could be overcome. Tensing the abdominal muscles, as in screaming, is of some value. An abdominal belt inflated to a pressure of about 75 mm. Hg for one-half minute before exposure to the expected acceleration increases acceleration tolerance by 2 to 3 "G's."

Environmental Temperature.—Overheating or heat exhaustion is rarely serious. Treatment consists of placing the patient in a cool place out of the sun, loosening tight clothing, and stimulation by cold water to the face or inhalation of aromatic spirits of ammonia.

Sunstroke or heat retention is serious and requires attention to water and salt metabolism, cool environment, rest, and external application of cool moist cloths. Since body temperature is lost by evaporation, convection, and conduction, all methods are utilized. The best results are obtained by the application of cold moist towels for thirty minutes and then their removal; the air is kept in motion by electric fans directed away from the patient. By this method the skin is cooled and thereby the peripheral blood. Then when vasoconstriction occurs the cold is removed, allowing blood to return to the surface for cooling which is augmented by the evaporation of surface water.

Shock from prolonged exposure to cold is best treated by rapid warming. This is obtained by merely placing the patient at rest in a warm room. Attention to water balance, nutrition, and blood volume is necessary.

Irreversible Shock.—Irreversible shock is a type that should be discovered by failure of treatment. In other words, no patient should be considered in irreversible shock regardless of time element, cause, or other factors. Every surgeon has seen the apparently "hopeless" case respond to vigorous scientific treatment and then go on to recovery. Even anoxia of five minutes or more may be followed by recovery, albeit often with a damaged cerebral cortex. There is no test which brands shock as irreversible, and even if there were the good physician would supply the patient with blood and oxygen in the hope that all tests may fail.

of the pleura and chest wall is necessary. Closed drainage is used by introducing a small catheter which is sealed to the chest and is connected by a glass adapter and soft rubber tube to an under-water seal. Evacuation of pulmonary secretion and blood is extremely important. Following the operation the anesthetist must aspirate secretions through the endotracheal tube; then bronchoscopy is done to suck out all portions of the bronchial tree. Until the patient is awake, he should be in the Trendelenburg position, 10 to 15 degrees. As soon as consciousness returns, the patient is allowed to sit up, his chest held by the nurse, and allowed to cough up retained secretions. Sometimes a catheter attached to a suction machine must be used to facilitate the removal of thick ropy mucus and old blood from the pharynx and upper trachea. Heavy doses of narcotics should not be given and the patient should sleep on the affected side. Oxygen should be discontinued as soon as possible.

Cardiac tamponade due to stab or bullet wounds of the heart demands immediate surgery with blood started slowly in an attempt to produce a reaction from shock. If blood is given too rapidly, and this can only be done if given under pressure or intra-arterially because of the high venous pressure, shock may be increased due to more blood in the pericardium. As soon as the pericardial sac is opened, shock is lessened; blood is given while the lesions are being repaired. Shock due to the accumulation of fluid from pericarditis is less severe and may be treated by aspirations or drainage.

Crush or Compression Syndrome.—The treatment of compression syndrome resembles closely the treatment of extensive burns. Since renal failure is the usual cause of death, the establishment of an alkaline diuresis is desirable. If the patient can swallow, large doses of sodium bicarbonate should be given (4 Gm. per hour until the urine is alkaline; then 30 Gm. per day for two days). Should vomiting preclude oral administration, 1 liter of isotonic sodium lactate (one-sixth molar = 2 Gm. per 100 c.c.) may be given intravenously, or sodium bicarbonate, 3.5 Gm., as available in sterile ampoule for intravenous use. An average of 3,000 c.c. of fluid should be given per day in the adult. This may be administered by hypodermoclysis into the injured area if the patient is unable to swallow.

Local treatment consists of pressure bandage or surgical intervention after reaction from shock. That is, if compression has produced gangrene, amputation may be necessary in an extremity, or local excision of necrotic areas may facilitate healing and delimit toxic effects. Shock is treated by restoration of blood volume with whole blood, plasma, or both. Anuria may occur in spite of treatment and therefore a close watch is maintained of urinary output. With established renal failure fluids must be restricted and here plasma or glucose solution, 5 per cent, is more useful than saline. The danger in patients with anuria is overhydration and pulmonary edema. Hypodermoclysis is safer than intravenous administration. (See Chapter 23 under Anuria.)

PART IV

REACTIONS OF TISSUES AND ORGANS TO TRAUMA OF UNKNOWN ORIGIN

Chapter 15

TUMORS AND CYSTS

Previous chapters have dealt with the reactions of different tissues to injuries of all kinds. We learned about repair following injuries which result from mechanical forces and bacterial invasion. Next we considered the reasons for delayed healing or lack of repair or destruction of tissue in the chapter on Ulcer and Gangrene. Miscellaneous bacterial causes for injury and the more or less characteristic type of reactions to such trauma were then reviewed. Lastly the behavior of the entire organism in its reponse to trauma which has widespread effects was discussed in the chapters on The Human Constitution, The Interchange of Body Fluids, Acid-Base Balance, Hemorrhage, and Shock. In this section of the book we are again endeavoring to describe the body's reaction to trauma. Unlike previous descriptions we are unable to name the cause of the injury, although its morphological and to some extent its biochemical and physiological effects are known. It follows, since we do not know all of the cause or causes nor the full effects of the injury, that prevention and treatment must rest entirely on empirical ground.

The body fights its adversaries with increased blood supply and cells—blood is the "life line" of fighting forces and cells are the fighters. Cells engulf, surround, erect fences (fibrous tissue) and block all roads (lymphatics and capillaries) which may lead to the escape of the enemy. Even in this weird, devastating and morbid process called neoplasia, the body fights back, and in the light of recent experiments this fight is beginning to be partially understood.

New growths were known to the ancients and are mentioned in Papyrus Ebers (1500 B.C.). The ancients treated them by excision and by escharotics, such as arsenical ointment. The latter were *temporarily* abandoned but have recently been revived. They may not completely remove the growth, but they do not spread it. The word cancer was originally used by Herodotus to mean any chronic growth or swelling. Hippocrates (460-375 B.C.) burnt out a carcinoma of the neck—the earliest record of diathermy. Neoplasms are widely disseminated in nature (lower animals, plants, trees) and are more common in civilized than in uncivilized peoples.

The word *tumor* means a swelling and though it might from its derivation be applied to inflammatory lesions, it is ordinarly used today to re-

duct of a gland. (Cysts will be discussed in one of the following paragraphs.) These swellings, with a few exceptions (such as cystadenoma), *are not neoplasms. Hypertrophy means an enlargement of the cell; hyperplasia* means the production of new cells. Simple epithelium when irritated may undergo metaplasia, becoming stratified. This is seen in the ciliated epithelium of the bronchi in chronic infections and of the uterus. Although the increase in the number or size of the cells results in an enlargement of the organ involved, the process in either case serves a useful purpose and is initiated because of an increased demand upon its function. It is governed by the normal physiological laws of growth. Thus, an adenoma may be the result of an attempt at hyperplasia and hypertrophy with subsequent fibrosis about the area as seen in the breast and thyroid.

Invasion and destruction of tissue is a characteristic of cancer. However, it is true that leucocytes invade tissues and so do the so-called trophoblasts in the early stages of pregnancy invade the body of the uterus. Unlike cancer, these cells when "mature" are sloughed and the uterine wall is restored to normal unless a cancerous process, chorio-epithelioma, supervenes.

Cancer is a process in which certain cells in an organized cell group become "wild," resembling early embryonic tissue morphologically, immunologically, and biochemically. But unlike normal embryonic tissue, differentiation does not occur; moreover, heterologous transplants of embryonic tissue may be successfully made up to the fifth month of *gestation. The same property exists in many cancers.*

TUMORS

Structural Characteristics of Neoplasms

New growths are spoken of as *histioid* or *organoid* in structure: histioid growths are composed of cells (for example, a lipoma or fatty tumor is *made up of fat cells*); *organoid growths are composed of organs (an* hemangioma is made up of capillaries; a dermoid tumor may contain teeth or hair; a teratoma contains fetal remains). The term *lepidic* refers to a growth in which the cells lie next to each other, as in epithelium or endothelium. *Hylic* growths contain cells separated by a matrix, as in connective tissue or bone. *Homologous* growths are those in which the tissue is like the organ in which they are growing, whereas *heterologous* growths are those in which an unlike or mixed type of tissue is encountered. An example of the latter would be a chondroma (a cartilaginous growth) found in glandular tissue; for example, in the breast or the parotid gland. New Growths may be *encapsulated,* in which case they are apt to be benign, or they may be infiltrative, in which case they are apt to be malignant. *Unicentric* growths have one place of origin; occasionally neoplasms are *multicentric,* as in the colon, with two or three points of

fer to new growths and cysts. The word *cancer* is commonly used to imply a malignant growth. *Neoplasm* means new growth, and *neoplasia* means the formation of new tissue. As the terms are usually employed, they mean that the new tissue is abnormal as to anatomy and physiology.

A new growth may be suspected in the case of any swelling which exists where it should not be or in the case of any chronic ulcer that does not heal according to the normal laws of repair. On the outside of the body this is easy to detect. In the internal organs we must depend on the history and symptoms, signs, a study of transudates, exudates and secretions for deciduous cells, x-rays, and endoscopy to help us. There are as many different kinds of new growths as there are different kinds of cells that occur in the body or in embryologic development. Therefore, neoplasms constitute a heterogenous group of anatomic defects which are as numerous as the different kinds of tissue.

We have said that repair is an orderly purposeful attempt on the part of nature to heal or to reconstruct continuity of tissue, both as to structure and, in some cases, as to function. The neoplasm, unlike repair tissue, has an independent character of development. This has been called *autonomy* or *self-determination* and is not fully understood, but it manifests itself in an *excess proliferation of tissue* or tissues which has no natural termination and serves no purpose. Although many normal cells cultivated in vitro possess autonomy, they lose this property when implanted in the animal body. When a new growth occurs in an endocrine gland the gland is sometimes stimulated to perverted activity or overactivity, as in pituitary adenoma (Cushing's disease) or parathyroid adenoma (hyperparathyroidism). Neoplasia is harmful to the general body economy and has no useful function. It acts like a parasite in that it derives its nourishment from the blood supply of the host and lives at his expense, but cancer cells are not supplied with nerves from the host. However, so far as is known, new growths are not parasitic in origin, although they are known to arise in tissues which have been the site of parasitic infection. In order to illustrate this point more clearly, we may give examples of other swellings which are not neoplastic.

Many infections produce tumorlike lumps such as *warts* and *condylomas* (flat growths usually associated with venereal infections); although these lumps may not have a useful function, yet they are classed as defensive inflammatory reactions to infection, which is not true of new growths. Epithelial cells have no other inherent method of defense except hypertrophy and hyperplasia. Condyloma accuminata are called forth by any irritation, whereas condyloma lata are due to syphilis. The former are thought to result from a virus. *Gigantism* is also excessive growth of tissue, but it is normal in architecture and in cellular content; therefore, the sum total of tissue is larger and greater, but it does not come under our classification of neoplasms. *Cysts* may be inflammatory in origin but are usually due to an obstruction of the principal

duct of a gland. (Cysts will be discussed in one of the following paragraphs.) These swellings, with a few exceptions (such as cystadenoma), are not neoplasms. *Hypertrophy* means an enlargement of the cell; *hyperplasia* means the production of new cells. Simple epithelium when irritated may undergo metaplasia, becoming stratified. This is seen in the ciliated epithelium of the bronchi in chronic infections and of the uterus. Although the increase in the number or size of the cells results in an enlargement of the organ involved, the process in either case serves a useful purpose and is initiated because of an increased demand upon its function. It is governed by the normal physiological laws of growth. Thus, an adenoma may be the result of an attempt at hyperplasia and hypertrophy with subsequent fibrosis about the area as seen in the breast and thyroid.

Invasion and destruction of tissue is a characteristic of cancer. However, it is true that leucocytes invade tissues and so do the so-called trophoblasts in the early stages of pregnancy invade the body of the uterus. Unlike cancer, these cells when "mature" are sloughed and the uterine wall is restored to normal unless a cancerous process, chorio-epithelioma, supervenes.

Cancer is a process in which certain cells in an organized cell group become "wild," resembling early embryonic tissue morphologically, immunologically, and biochemically. But unlike normal embryonic tissue, *differentiation does not occur; moreover, heterologous transplants* of embryonic tissue may be successfully made up to the fifth month of gestation. The same property exists in many cancers.

TUMORS

Structural Characteristics of Neoplasms

New growths are spoken of as *histioid* or *organoid* in structure: histioid growths are composed of cells (for example, a lipoma or fatty tumor is made up of fat cells); organoid growths are composed of organs (an hemangioma is made up of capillaries; a dermoid tumor may contain teeth or hair; a teratoma contains fetal remains). The term *lepidic* refers to a growth in which the cells lie next to each other, as in epithelium or endothelium. *Hylic* growths contain cells separated by a matrix, as in connective tissue or bone. *Homologous* growths are those in which the tissue is like the organ in which they are growing, whereas *heterologous* growths are those in which an unlike or mixed type of tissue is encountered. An example of the latter would be a chondroma (a cartilaginous growth) found in glandular tissue; for example, in the breast or the parotid gland. New Growths may be *encapsulated*, in which case they are apt to be benign, or they may be infiltrative, in which case they are apt to be malignant. *Unicentric* growths have one place of origin; occasionally neoplasms are *multicentric*, as in the colon, with two or three points of

growth occurring simultaneously. Although the latter are usually benign, multiplicity of origin is seen in malignant growths as well. These may be in the same organ or in paired organs or in widely separated areas.

Manner of Growth.—Tumor cells multiply by mitotic division or by amitosis, or direct division may occur, but if so it is rare.

A. *Expansive* growth is characteristic of benign neoplasms. As they grow they push aside the adjacent tissue. (Lipoma, fibroadenoma, etc.)

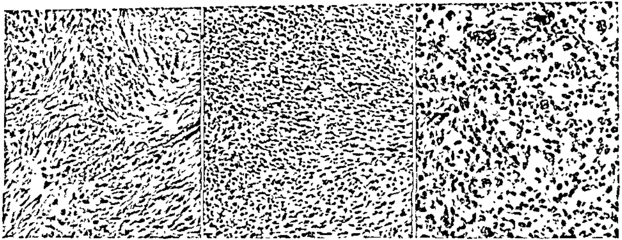
B. *Central* growth progresses in a centripetal manner; in other words, the oldest tissue is that around the edge (fibromyoma, etc.). Growths by expansion of the original mass follow this plan of growing principally in the center of the tumor; therefore, A and B usually go together.

C. In *peripheral* growth the actively growing cells are around the periphery. This may be termed a centrifugal type of growth, with the oldest tissue in the center. This makes eradication more difficult. It is sometimes seen in benign tumors (chondroma), but is usually a characteristic of malignant neoplasms.

D. *Extensive* growth extends or spreads to contiguous tissues without complete involvement of intervening structures. (Proliferating papillary cystadenoma and Krukenberg tumor.)

E. *Infiltrative* growth spreads and invades adjacent tissues and structures, as in carcinoma of the cervix, where first the entire cervix, then the ureters, the bladder, and the broad ligaments are invaded. Thus neoplastic buds or projections enlarge, fuse, and destroy intervening tissue, including blood and lymph vessels, thereby providing for their dissemination. Infiltration may be due to pressure, interference with blood supply, or infection. A tumor may look hopeless at operation, but microscopic studies may show infiltration which is not due to neoplastic cells but rather to inflammation, and the enlarged lymph nodes may also be inflammatory rather than malignant.

Character of the Cells.—Neoplastic cells may resemble normal cells or they may resemble their primitive forebears; namely, cells of the embryological tissue from which they are derived. The more nearly a neoplasm resembles normal tissue, the less malignant it is, and the contrary is true. Some have based their diagnosis as to malignancy on this fact. This has been called Broder's classification. If the majority of the neoplastic cells in a growth resemble the normal, the growth has been called type I, whereas in those growths in which the majority of the cells are definitely embryonic in type, the growth has been called type IV. Types II and III are intermediate between I and IV. Dukes' classification is useful in neoplasms of the large intestine and is based upon the degree of invasion. In type A the growth is limited to the wall of the intestine. In type B it has extended to the outside and has involved extracolic or extrarectal tissue. In type C the growth has spread to ad-



A. B. C.

Fig. 110.—Spindle-cell sarcoma; fibroblastic sarcoma. *A*. Low grade of malignancy. Cells are of the adult type; cell fibrils are abundant (fibrosarcoma). *B*. Moderate degree of malignancy. There is increased cellularity with less intercellular substance. The cells are much smaller than normal fibroblasts (small spindle cells). *C*. Highly malignant large spindle-cell sarcoma. The loosely arranged cells are atypical in size, shape, and staining reaction. Note malignant giant cells at the top.

jacent lymph nodes. A fourth type, D, would include metastasis to the liver. Neoplasms are also spoken of as *more* or *less* atypical in structure or arrangement, the former being malignant, the latter tending to be benign.

Neoplastic tissue is made of *cells* and *stroma*. The latter makes up the framework and carries the blood supply. This comes from the host and is commandeered by the neoplasm.

Neoplastic cells are usually round and have more deeply staining nuclei than normal cells. Their function is abnormal in respect to the production of fibers, matrix, or secretion. However, some of the less malignant do have a primitive function, such as the production of mucous (mucus adenocarcinoma) or the production of bone (osteogenetic sarcoma). We may readily deduce that these latter types of growth are apt to be less malignant than those which destroy rather than produce a secretion or substance, however, primitive the secretion may be. That is to say, if the neoplasm produces any form of secretion or tissue, it approaches the adult as distinguished from the embryonic type. Sometimes epithelial cells are displaced due to attempts at repair, into a new environment. Thus buried epithelial cells are seen in chronic ulcers of the leg, etc. In the colon these cells are found in the submucosa as isolated groups which may form a cyst or a neoplasm due to their altered environment. Such cells may therefore vary from normal to widely aberrant epithelial cells.

The word *anaplasia* has been used to describe the primitive type of cell and means a reversion to the embryonic state (*ana*, against; *plasia*, growth).

The word *dedifferentiation* has been used to mean the same thing. The thought that this word conveys is that instead of a cell's growing from its primitive embryonic form into an adult cell, it does exactly the opposite: it "dedifferentiates" into its primitive forebear. Most observers agree that mammalian cancer cells are derived from normal cells. Ewing states:

> Striking peculiarities in such a fundamental process as cell division may well *suggest that here is disclosed the essential nature of tumor growth.* Hansemann has interpreted the studies in this field in such a manner, holding that asymmetrical, multipolar and abortive mitoses mean unequal distribution of cell potencies, loss of cell differentiation, freedom from normal restrains to growth, and exaggeration of *growth* over functional capacities. These physiological properties he included in the conception of *anaplasia,* the morphological side of which is illustrated in resting and dividing tumor cells.

The majority of tumor cells, according to Ewing, divide by normal mitosis: abnormal mitoses are secondary results of tumor growth.

Malignancy and Benignancy.—*A benign or "innocent"* growth is one that is encapsulated and is therefore freely movable in the tissue. Its cells resemble the normal, and the tumors are usually multiple. Growth is

Fig. 111.—Papilloma. The epithelium shows a great amount of infolding but there is no penetration of the basement membrane.

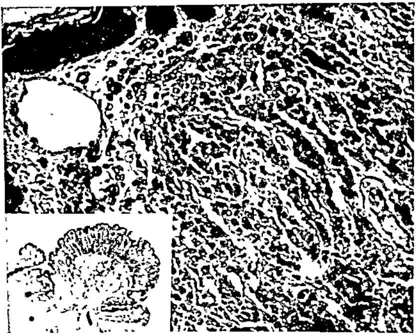


Fig. 112.—Papillary nevus (elevated pigmented mole). The low power shows the lack of invasiveness indicating its benign nature. The high power shows the chromatophore cells. Nerves are also seen. These tumors are frequently found in von Recklinghausen's disease.

extremely slow (months or years), and if death should ensue it would be caused by the interference of the growth with some vital function due to its location and size rather than to a destruction of tissue. An example of this would be a benign growth in the brain or in the esophagus or bronchus.

A malignant growth is usually, though by no means invariably, single; its growth is rapid (weeks or months); it is fixed in the tissue because of its infiltrative growth. It often degenerates and ulcerates, and it may spread to other parts of the body. Hemorrhage and disturbance of function are common, and in its later stage a state of disability, known as cachexia, ensues. Such a growth is apt to recur after being removed unless the removal is thorough, complete, and early. There is generally no capsule and the growth may be very vascular and meaty. Areas of hemorrhage and necrosis are encountered, and the edge shades off into the surrounding tissue. Bleeding is an early symptom due to friability.

Under the microscope we see, first, cells—cells everywhere—with little or no stroma; dedifferentiation cells (anaplasia), with variation in size, shape, and staining reactions; a very few thin-walled blood vessels; and the inclusion of fragments of surrounding tissue (showing the growth's infiltrative character). Evidence of rapid growth is found in the mitotic figures that are encountered. (These occur in cells in which the nucleus is dividing.) In other words, the growth is abnormal in respect both to the cells and their architectural arrangement.

On the basis of his experience with over 50,000 neoplasms, MacCarty recognizes three great groups: (1) those neoplasms composed of adult cells, with normal tissue arrangement; (2) those composed of cells normally, or nearly normally, arranged but having the morphology of malignant, regenerative cells; and (3) those composed of cells of the malignant, regenerative type, not arranged in any fashion approaching that of any normal tissue. Clinical experience has shown that neoplasms of the first group are not invasive and do not metastasize. They interfere with the function of the organ or tissue containing them and sometimes, by their extensive growth, interfere with neighboring structures. They are spoken of as being clinically benign, although they not infrequently kill their host, and are, therefore, in a sense, just as malignant as groups 2 and 3. Such terms as adenoma, osteoma, neuroma, myoma, and chondroma have been applied to tumors in this first group. The second and third groups embrace the so-called clinically malignant tumors, the adjective "malignant" usually connoting invasion of normal tissues by the new cells and migration of the new cells to other parts of the body, thus forming metastases. From a practical standpoint there is no great clinical difference between group 2 and group 3. Both are malignant and both kill the host. The only differences are the histological pictures and the usual greater malignancy of group 3. The therapy for the two

groups is the same. Transformation of a benign to a malignant growth may occur in rare instances, as in congenital polyposis of the colon. It is generally agreed, however, that there is less chance of a malignant growth developing in a benign tumor than there is of a malignant tumor growing in an area not previously tumorous.

The word *metastasis* is of Greek derivation. *Meta* means "in the midst of," and *stasis* means "a placing." As commonly used, it means the dissemination of neoplastic cells into different portions of the body. This may occur in two ways: (1) by way of the lymphatics and (2) by the blood stream.

Fig. 113.—Neurofibromatosis (von Recklinghausen's disease).

Lymph metastasis is usually encountered in carcinoma (malignant epithelial growths). It may take place in two ways: by embolism or by permeation. (1) *Embolism* refers to a cell's or groups of cells' breaking off and being carried by the lymph vessels to the anatomically related lymph nodes. Since the lymph channels enter the lymph node peripherally, through the cortex, such cells will be found in the cortical portion. An example of this type of metastasis is epidermoid carcinoma of the lower lip, where cells do not involve the chin but deposit themselves in the submental lymph nodes. (2) *Permeation* is a process which has been made clear by the work of Sampson Handley. (Chapter 16, Carcinoma of the Breast.) The cells grow along the wall of the lymph channel and by retrogressive growth infiltrate the superficial lymphatics of the surrounding tissues, the reticular lymph vessels as well as the tubular. This permeation is carried along the deep fascia upon which the tubular lymphatics lie, finally involving the lymph nodes. This per-

meation causes a *perilymphatic fibrosis* (Chapter 17). The process has been compared to the spread of a prairie fire, whereas embolism is like the flight of a bullet. Small lymph vessels are easily plugged by cancer cells which break through, causing perilymphatic fibrosis. Large lymph vessels carry groups of cells as a unit—that is, as emboli. Carcinoma of the breast spreads by permeation (Chapter 16). It is easy to understand that in metastasis by embolism the surgeon would be required to remove the primary growth and the lymph nodes involved, whereas in metastasis by permeation he would be required to remove the growth and in addition a wide area of skin and all intervening fascia (on which the lymphatics lie) as well as the lymph nodes involved.

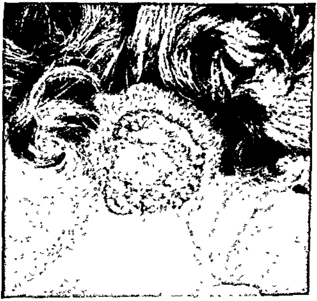

Fig. 114.—Squamous-cell carcinoma of the neck. Note the elevated margin.

Blood stream metastasis is more commonly encountered in sarcoma (connective tissue malignancy) than in carcinoma. Here a group of cells breaks off after penetrating the thin-walled veins and is carried quickly to the lungs. If a sarcoma has metastasized, it is hopeless. No matter how thorough the surgery may be, cure will be impossible unless some new carcinotoxic agent is forthcoming. Such neoplasms as those of the thyroid and testis and malignant melanoma or lymphosarcoma metastasize in both ways. These are particularly malignant. The surgeon should always look for metastatic growths before operation is attempted. Such growths may be found upon x-ray of the lungs and bones or palpation for "sentinel" nodes in the supraclavicular region. Metastatic masses may be found in the pararectal fossae (Blumer's shelf), the pouch of Douglas, or the umbilicus. An enlarged liver (nodular) with ascites may be discovered.

Malignant neoplasms may metastasize also in peculiar and bizarre combinations of ways. The coelomic cavity is frequently invaded by can-

cer which originates in the lungs, bronchi, or gastrointestinal tract and also by malignant growths outside the thorax or abdomen such as cancer of the breast. The pleura and peritoneum have very little capacity to arrest cancer; hence once invasion has occurred the malignant process spreads rapidly. Intrapericardial invasion is usually by direct extension from the lungs, bronchi, or breast. The cerebrospinal spaces are invaded by carcinoma of the breast and may spread throughout this area resembling a cerebrospinal meningitis in symptomatology. Invasion of the blood stream is common for sarcomas, but their involvement of lymphatics is rare except in lymphosarcoma. This is probably due to the greater local fixation of sarcoma cells as compared with the mobile and sometimes ameboid cancer cell (Ewing). This is the reason that lymphosarcomas behave much like carcinomas. Also, sarcomas are more vascular than carcinomas so that cells may invade and break into the thin-walled blood vessels. Finally the growth of sarcomas is more expansive and encapsulated so that lymph vessels are closed but nutrient blood vessels are open. The invasion of the blood stream may occur by the following avenues:

1. Direct involvement of vessels by primary or secondary tumors.
2. Secondary embolism; that is, emboli arrested in the lung may grow through the vessels and break into the pulmonary veins.
3. Tertiary embolism; that is, metastatic tumors in the liver, producing pulmonary emboli.
4. Retrograde transport as distinguished from Handley's permeation theory means that emboli actually travel against the blood or lymph current. Retrograde transport occurs chiefly in those organs with a normal venous pulse (lungs, liver, kidneys, heart, and brain) and in which violent changes in intrathoracic pressure may transform the weak forward into a backward current. When the main lymph or blood channel is occluded, backward transport may occur more commonly in the latter, although collaterals should prevent this. Retrograde metastases may start from tumors within or without the organ involved. Examples: a large tumor thrombus from primary sarcoma of the tibia lying in an arched vein of the kidney could originate only by backward passage through the renal vein of an embolus traveling from below; emboli in a cerebral sinus with cancer of the breast, in an hepatic vein from intestinal or thyroid cancer, and in cerebral, cardiac pulmonary and hepatic veins in hypernephroma; through the lymphatics—bronchial nodes with subpleural lymphatic invasion but without pulmonary parenchyma involvement; gastric carcinoma with involvement of portal, lumbar, and inguinal nodes may be retrograde or by permeation.
5. Paradoxic embolism by way of a patent foramen ovale.
6. Passage of single cells through pulmonary venules.
7. Through the thoracic and right lymphatic ducts.

Metastasis of benign tumors is probably a misnomer. However, it is seen in metastasizing "adenomas" of the thyroid. Such growths may invade surrounding tissues so that extirpation is as impossible as in late carcinoma of the thyroid. Yet the microscopic studies show "fetal adenomas" and adenomatosis with hyperplasia and great vascularity. We are not sure that these are benign "adenomas." Bronchial adenomas, chondromas (these may come from a teratoma not so recognized) and leiomyoma of uterus are usually listed as benign growths. However, the element of malignancy is difficult to rule out in these tumors, particularly the bronchial adenomas.

Fig. 115.—Squamous-cell carcinoma (prickle-cell cancer) of the finger. The low power shows the ulcer and the invasive character of the growth. The high power shows epithelial pearl and malignant cells. Note the intercellular bridges.

Some general observations on metastases are:

1. Most squamous carcinomas of the head and neck spread to the cervical lymph nodes but rarely below the clavicle. Practically none show distant metastasis without first having cervical node involvement.

2. Distant metastases from cancer in the upper respiratory and alimentary tract, due to blood-borne metastases occur in about 23 per cent. The most common sites are lungs, liver, and pleura in the order named.

3. Patients with cancer of the mucosa of the cheek, gingiva, palate, nasal cavity, and esophagus show the greatest incidence of systemic dissemination of primary lesion.

4. The morphology of the tumor gives no hint as to the probability of distant metastases but the age does. The younger patients show the greatest tendency.

5. Supraclavicular lymph node involvement from abdominal and thoracic cancers is uncommon. The sentinel or Virchow node is not often affected. When it does occur it is more frequent on the left than on the right where it occurs mainly in patients with thoracic cancer. Both supraclaviculars are involved still more rarely and practically always from thoracic malignancies. Although these nodes may be the *first* clinical signs of thoracic or abdominal cancer, in most cases generalized metastases have already occurred at the time that the cervical nodes are involved.

6. Lymph node involvement may be the first and only symptom of cancer. We have seen this in cervical nodes especially in cancer of nasopharynx, axillary nodes in scirrhus carcinoma of the breast, inguinal nodes in carcinoma of anus and vagina.

7. Every swelling in the neck, axilla, or inguinal region must be considered seriously as a probable tumor enlargement due to metastatic node involvement. Although primary growths and node involvement due to other causes must be considered (Chapter 17), the fact that the swelling is a metastatic node must be kept in mind. An accurate knowledge of anatomical node arrangement, a careful history, and repeated examinations may reveal the hidden cancer. Biopsy should be reserved for the last, not the first, means of diagnosis.

Theories as to the Cause of New Growths

The cause or causes of new growth are not known. However, it is correct to assume that as in other surreptitious invaders, it takes two to make the bargain—The carcinogenic factor and the resistance or lack of resistance of the host. Ewing spoke of the *causal* genesis of tumors including the inciting agents leading up to the development of malignancy and the *formal* genesis or the factors responsible for the nature of the cancer cell and its tendency to autonomy. These two factors, the remote extrinsic or contributory and the proximate intrinsic or actual causes, constitute as in all diseases the problem of carcinogenesis. Let us first consider some of the older concepts and then the more modern interpretations of the cause of neoplasia. At the outset we must remember that much of the recent work is being done on experimental animals and since there is great variation in susceptibility and behavior of different lower animal groups and species there obviously may be a great difference between the findings in mice and the effect on man. In this review we shall attempt to integrate these findings wherever possible.

Cohnheim spoke of *cell rests*, by which he meant the enclosing in normal tissue of a group of embryonic cells which may suddenly take on new growth. We may liken this to a new building in which brick and mortar may be mislaid in various areas during construction. This explains the structure of such growths as dermoids and teratomas, but we are totally unable to explain why the misplaced cells suddenly take on wild and unlimited growth.

Ribbert believed that one component (the cells) grows because the other (the stroma) does not restrain. Little has recently reaffirmed this theory stating that carcinogenic agents act by removing inhibitory influences to cell growth and production. Thiersch said connective tissue fails as old age approaches. Some observers aver that neoplasia is "repair gone wrong." It starts as normal repair and does not have the restraining influence necessary to stop proliferation. Waldeyer believed that *connective tissue grows rapidly and aberrantly and irritates epithelium* into activity.

Genetic Factors.—One of the most important studies on the cause of cancer is the role played by hereditary transmission, or inherent predisposition to the disease. Does the formal proximate intrinsic or actual cause of neoplasia reside in a certain constitutional type or is it inherited, and, if so, are there any laws of heredity which it follows? How shall we answer this question when asked by a patient who is a descendent of a cancer family. Evidence for this by no means simple question comes from statistics on cancer, histories of families, study of twins, experimentation on animals, and the response of cancer strains to carcinogenic agents.

It was formerly taught that in lower animals at any rate carcinoma may be trans*mitted as a recessive character and will occur in the second generation in strict mendelian* ratio and that transmission may be through either sex but more commonly through the female. MacDowell states that dominance is only a special case at the end of a cutaneous series of interrelations between pairs of genes. No gene can produce its effect without cooperation of many other genes—and genes and extrinsic conditions cooperate in all cases. By inbreeding, involving brother to sister mating, many different strains of mice have been established with varying degrees of susceptibility to cancer. This genetic homogeneity shows among other characteristics that the inherited tendency or predisposition to develop cancer is not a general character but is confined to a *definite organ* or tissue type. Only in primary cancer of the lung (in mice) is the inheritance a hereditary dominant character although the dominance is incomplete. Tumors of different sites and types differ in their genetic behavior (see Chapter 10).

Some people are susceptible; that is, they react to stimuli (as yet not defined) with tumor formation. Others are refractory. In the former, factors exist which are inherited independently of a general disposition which govern the localization of the disease due to favorable local soil; such an individual with both general and local susceptibility is apt to get cancer. This is illustrated by studies in families with cancer in Holland and Norway. Patients with the disease, "basal patients," have brothers or sisters (siblings) or brothers, sisters, parents, aunts, and uncles with the disease much more commonly and at an earlier age than in "non basal" families; *this holds true for* a particular organ as well. Waaler has shown that in 100 women with cancer of the breast who had a sister with cancer, 45 would have cancer of the breast. Of 100 women with cancer elsewhere in the body with cancerous sisters, only 16 had cancer of the breast—*the general incidence. A study of 53 monozygous and 35 dizygous* twins was reported in which tumors occurred in one or both. The incidence in both members was greater in the former. The tumor was of the same type and occurred in the same organ and the age of onset was more nearly identical much more frequently in the monozygous than in the dizygous twin group.

Host Factors in Cancer.—A variable group of so-called host factors have been mentioned as contributing to susceptibility to cancer; among these are age, race, body weight, diet, and even social strata.

Age as an etiological factor is important, although only relatively so, because we now see cancer in much younger individuals than formerly. However, we may state that it is primarily a disease of those over, rather than under, 40 years of age. It is interesting to note in this connection that when carcinoma occurs in patients in the second and third decades of life, there is very rapid metastasis, whereas *in patients in* the seventh and eighth decades, there is a very slow one. The reverse is true of infec-

tion. *Thus, the older an individual, the less resistant the lymphatics to the spread of infection and the more resistant to the spread of neoplasms.* We do not know the cause of this difference. Since carcinoma occurs usually in the fifth and sixth decades, the difference in rate between the spread of infection and neoplasm is not apparent, because this is the middle ground. As we grow older there is an accumulation in certain older tissues of stimuli to growth and a sensitization as a result of these stimuli which are either hormonal or nonhormonal within the cell itself.

Fig. 116.—Malignant dermatosis. Clinical photograph of Bowen's disease of the skin or malignant dermatosis. (Carcinoma in situ of the skin.) Note the many areas of carcinomatous tissue, yet there are no metastases. Apparently all of these areas and progressing simultaneously. The patient had many operations, and the lesions were so numerous that it was deemed inadvisable to remove more than a few lesions at a time for fear of denuding too large an area of the skin.

The tissues of older and those of younger organisms seem to differ only quantitatively in their reactions as far as growth processes and cancerous processes are concerned. This quantitative difference is sufficient to make of cancer in the young a highly malignant, rapidly killing disease, whereas the same growth in the old *may* be so slow in its growth as to assume benign proportions. Cancer is slow to evolve. If it appears in the young there is a strong susceptibility and a powerful carcinogenic agent, a combination which makes the resulting cancer highly malignant. If the conditions are reversed,

cancer may not develop until a late age. *This accounts for the greater incidence in the older group.* Thus the longer the individual lives, the greater his chance of getting cancer. The mouse lives 2 years, the human being 70 years. Therefore, in speaking of 6 months of age in the former, we mean about 17 *years in the latter. If aging is a* process of disorganization and disintegration the disorganized cells producing cancer resemble not the old cells but rather youthful, even embryonic cells.

Different species of animals show various susceptibilities to cancer. Moreover, a greater variety of species is subject to the carcinogenic process than to any other disease. Spontaneous cancers have been found in insects, birds, reptiles, amphibia, fish, mice, rats, rabbits, dogs, cats, cattle, hogs, and sheep as well as in man.

Cancer of the skin is far more common in the white than in the colored race; there is nearly a total absence of gastric cancer in the native Malay population of Java, although the Chinese in Java have it; primary liver cell cancer is common in Java and Sumatra and in certain populations of Africa including the Bantus and the natives of Northern India, whereas it is uncommon in Europe and America. Japanese women have an extreme incidence of cancer of the uterine cervix (32 per cent) but a very low incidence of mammary cancer (3 per cent).

In both animals and man individuals of average or less than average weight are thought not as likely to develop cancer as those who are overweight; this is not unequivocally proved. *However, diet may play a role as a modifying factor in carcinogenesis.* The growth rate of spontaneous mammary carcinoma in mice is inhibited by diets deficient in certain essential amino acids (Voegtlin); hepatoma formation by butter yellow *has been observed; methylcholanthrene painted on the skin* of mice will produce acute leucemia if their diets have adequate amounts of cystine; on low cystine diets leucemia is greatly retarded and instead sclerotic lesions of the larger arteries are observed (Voegtlin).

The fact that cancer was found to be more prevalent in the lowest social class in England twenty years ago led to group studies of class incidence. Much of this data is now known to be the result of extrinsic occupational carcinogenic contacts. Cramer believes that "social cancer" is an experiment carried out by man on himself in his ignorance, and with increasing knowledge of the exogenous factors involved it should, like occupational cancer, become a preventable disease.

Carcinogenic Agents.—

Exogenous Causes.—The number of provocative carcinogens is so great that many can only be mentioned here. Indeed carcinogenicity is influenced by such factors as species, genetic constitution, age, sex, diet, physical condition of the animal, purity of the chemical compound, dose, physical state of the compound, nature of the solvent or vehicle used, and site of application. If, however, there is an inciting agent for every spontaneous tumor, we must attempt to find it. Some of the agents are already known. Substances which produce cancer in any animal are known as pancarcinogens; some examples are certain of the polycyclic hydrocarbons (methylcholanthrene, benzpyrene), x ray, gamma ray of radium. *Provocative carcinogens bring about changes in tissues* which may or may not cause tumors. Most carcinogenic agents belong in this group. Rous calls the viruses actuating carcinogens. Some agents excite specific tissues to tumor formation: betanaphythylamine affects urinary bladder epithelium; estrone in experimental animals affects breast and uterus.

Occupational inciters include chemical and physical agents such as arsenic, chromates, nickel, carbonyl, radium, mesothorium, asbestos, crude mineral oil, pitch, tar, soot, paraffin oil, anthracene oil, creosote, aromatic amino compounds such as *aniline*, nephthylamine and benzidine, benzol, ultraviolet rays, roentgen rays, rays of radioactive substances including the atomic bomb, certain parasitic worms.

Habits and environmental stress may be responsible for cancer of the mouth, lips, and cheeks in tobacco smokers, betel nut chewers in Siam, fishermen holding tarry needles in their mouth in repairing nets, for cancer of the skin of the abdominal wall in

carriers of certain heating appliances in Kashmir or in Japan—kangri cancer, mule spinners cancer in England, exposure to the sun and wind in "outside" workers.

Trauma has usually been considered as a primary cause of cancer by patients as well as by physicians. Women with cancer of the breast usually recall an injury to the affected breast. "Chronic irritation" while still invoked for cancer control education lacks scientific confirmation experimentally or clinically. One often wonders why the little toe which is irritated by ill-fitting shoes to such degrees that *corns, calluses,* and deformities result is almost never the site of carcinoma. *Single* trauma as an etiologic factor in carcinoma is difficult to prove. At present this question has great medicolegal interest. Our own feeling is that if a single injury is the cause, then such an injury when induced by incomplete surgical removal of a benign neoplasm should

Fig 117.—Bowen's disease of skin (malignant dermatosis). Medium-power photomicrograph of skin in Bowen's disease. *A.* Hyperkeratotic epithelium and leucocytes forming a scab over the lesion. *B.* Malignant acanthotic germinal layer. *C.* A papilla of the dermis showing increased vascularity and many inflammatory cells. *D.* Enlarged rete peg showing irregularity of cell structure. It will be noted that there is no breaking through of the malignant area into the underlying tissue. (Squamous-cell carcinoma in situ)

result in a malignant growth. Marjolin called attention to the fact that not infrequently carcinoma arises in the chronic ulcer following a burn in the lower extremity. This may be cited as a single trauma supplemented by chronic irritation. The incomplete removal of melanomas composed of pluripotential chromatophore cells is followed by malignant melanoma often enough to make one wonder whether or not here is an exception to the fairly accurate observation that single trauma is not often the cause of cancer.

Infections may be cancer inciters as discussed under the heading of Endogenous Causes. An old observation which is fairly accurate is the infrequency of cancer in

cancer may not develop until a late age. This accounts for the greater incidence in the older group. Thus the longer the individual lives, the greater his chance of getting cancer. The mouse lives 2 years, the human being 70 years. Therefore, in speaking of 6 months of age in the former, we *mean about 17 years in the latter. If aging is a* process of disorganization and disintegration the disorganized cells producing cancer resemble not the old cells but rather youthful, even embryonic cells.

Different species of animals show various susceptibilities to cancer. Moreover, a greater variety of species is subject to the carcinogenic process than to any other disease. Carcinogenic Agents.—

Exogenous Causes.—The number of provocative carcinogens is so great that many can only be mentioned here. Indeed carcinogenicity is influenced by such factors as species, genetic constitution, age, sex, diet, physical condition of the animal, purity of the chemical compound, dose, physical state of the compound, *nature of the solvent* or vehicle used, and site of application. If, however, there is an inciting agent for every spontaneous tumor, we must attempt to find it. Some of the agents are already known. Substances which produce cancer in any animal are known as pancarcinogens; some examples are certain of the polycyclic hydrocarbons (methylcholanthrene, benzpyrene), *x ray, gamma ray of radium.* Provocative carcinogens bring about changes in tissues which may or may not cause tumors. Most carcinogenic agents belong in this group. Rous calls the viruses actuating carcinogens. Some agents excite specific tissues to tumor formation: betanaphythylamine affects urinary *bladder epithelium; estrone* in experimental animals affects breast and uterus.

Occupational inciters include chemical and physical agents such as arsenic, chromates, nickel, carbonyl, radium, mesothorium, asbestos, crude mineral oil, pitch, tar, soot, paraffin oil, anthracene oil, creosote, aromatic amino compounds such as aniline, nephthylamine and benzidine, benzol, ultraviolet rays, roentgen rays, rays of radioactive substances including the atomic bomb, certain parasitic worms.

Habits and environmental stress may be responsible for cancer of the mouth, lips, and cheeks in *tobacco smokers, betel nut chewers in Siam, fishermen* holding tarry needles in their mouth in repairing nets, for cancer of the skin of the abdominal wall in

augmented by a virus. When such a growth is pent up under the foreskin aided by inflammation and maceration, it may become malignant.

Animals may develop an immunity to viruses. Rabbits in which carcinoma is transplanted become strongly immune to the virus as the growths enlarge. Viruses require only slight tissue preparation (trauma of susceptible tissue with the virus) and therefore cannot be the cause of tumors generally. *There is no proof today that any human malignant tumor is induced by a virus.* Attempts to cause cancer with tumor tissues or tissue juices from man has failed and there is no record of a nurse's or a physician's acquiring sarcoma or carcinoma by contact unless the incubation period is a matter of years. Crude tissue extracts reported to have carcinogenic qualities are all associated with lipids or fats—in animals, extracts from tumors, liver, bile, urine, and lungs have produced tumors.

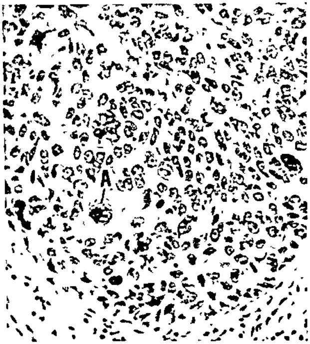

Fig. 118.—Bowen's disease of skin (malignant dermatosis). High-power photomicrograph of a rete peg shown in the previous illustration Note the nuclear agglutination and irregularity in size and shape of the nuclei. Note that the cells have been retained within the rete peg and have not infiltrated into the underlying tissue.

A, Large and multiple nuclei of a neoplastic, squamous epithelial cell. Bowen's disease. illustrates a type of squamous-cell carcinoma which is multicentric, which does not metastasize until very late. The reasons advanced for its peculiar behavior have been that there is very much tissue reaction about the new growth (round-cell infiltration and fibroplasia) so that it does not reach the lymphatics and is, therefore, not disseminated by them.

Carcinogenic agents from human sources include cholesterol and other sterols, the sex hormones, D vitamins, bile acids, myelin, and others. They have been mentioned under exogenous causes. However, when such compounds are present in excessively large amounts in the body, they may become endogenous carcinogens. The action of sex hormones in this capacity may arise from the following: (1) By stimulating gland tissue to develop they provide the cells on which other carcinogenic agents may act. (2) If supplied in excess they may themselves produce the tissue disorder out of which tumors come. (3) They may urge neoplastic cells on so that they multiply into tumors as in prostatic cancers which regress after orchiectomy. (4) They may act in combinations of the foregoing.

patients who have had a severe infection such as typhoid fever, scarlet fever, or other streptococcic septicemias. The use of Coley's mixed toxins (Bacillus prodigiosus and *Streptococcus erysipelatis*) in the treatment of sarcoma is based on this concept or on the phenomenon of Arthus and Shwartzman. A very interesting disease supposedly viral in origin occurring in South African sheep gives rise to a pulmonary adenomatosis known as Jagziekte. It is contagious among sheep and is known among sheep herders as "snotty nose." The important facts about this disease are that it occurs in man and is probably a multicentric malignant tumor of epithelial origin in the alveoli of the lung—an alveolar-cell carcinoma. Metatases are almost unknown. In this regard it resembles multiple malignant polypi of the colon or multiple squamous-cell carcinomas of the skin. The disease Jagziekte is contagious in sheep and the incubation period is relatively long. Is this disease and other forms of lung cancer contagious in man and not recognizeable as such because of the very long incubation period which extends over years rather than days or weeks?

Stimulation of certain tissues by trauma as well as by hormones will induce growth—not necessarily neoplasia. An organ or tissue increases in size by (1) increased blood supply, (2) increase in tissue fluids, (3) enlargement of cells (hypertrophy) and increase in numbers of cells (hyperplasia). Swabbing the vagina in mice stimulates growth of cells and new cells from two to more than twelve layers in forty eight hours. The chronic disturbance on which carcinoma arises is not known.

Exogenous agents may affect cells grown outside the body. Rat and mouse fibroblasts grown outside the body in a medium containing methylcholanthrene are changed into cells which resemble cells in cultures of sarcoma induced by this substance when injected into the subcutaneous tissue of rats. The transformation is irreversible. In turn the fibroblasts subjected to this action can produce sarcoma when injected into mice, even if done months after exposure, thereby eliminating a carry-over of the chemical. This same substance may induce mammary cancer.

Normal cells and their descendants can be made cancerous in vivo and in vitro but they cannot be made normal again. Once cancer is produced or occurs it cannot be reversed or stopped unless destroyed or removed.

Endogenous Causes.—Viruses may be exogenous or endogenous, but one type is definitely from sarcoma. Peyton Rous has produced chicken sarcoma by transplanting a substance thought to be a filtrable virus. Perhaps some of the tissue juice is the provocative agent. Rous contends that the only carcinogenic agents which are known to produce tumors by direct action are the neoplastic viruses. Agents which call forth carcinoma and sarcoma evoke a wide variety of neoplasms—from the most malignant to some which have so little initiative that they need help to survive. Therefore, the benign tumor and the cancer are only individual expressions of a single neoplastic principle. Deviations from this principle, as Kaposi's sarcoma (xeroderma pigmentosum), are rare. Normal cells while functioning may behave for a brief while as if neoplastic—the chorion, for example. The agents which call forth tumors in experimental animals are probably not the actuating causes of the growths they call forth. Many of them may be gone months or years before tumors develop. Animal parasites causing growths such as tubercle bacilli, Bilharzia, cysticercus (sarcoma from cyst wall in rat livers) are left behind as the tumors, which they may have started, enlarge. The irreversible intracellular change, once it has occurred, persists within the cell even after the carcinogenic agent has been removed or eradicated. Thus the autonomous infiltrative growth of the cancer cell is a property residing in the cell. Rous believes that viruses render normal cells neoplastic when injected in experimental animals and they maintain a partnership with them. All were originally gotten from spontaneous tumors and they give rise to growths like those from which they came. They are specific and act only on closely related species. Sometimes they may be provocative instead of actuating as in condyloma accuminata which we have seen is the result of irritation perhaps

cancer. The body resists excess of estrogen by detoxification; a part of this task is done by the liver. It is difficult to see how estrogenic hormones given in therapeutic doses to normal women could act as carcinogens. There are exceptions to this statement, such as bleeding from the nipple, metrorrhagia, etc., which will be discussed in other chapters. Recently a case of cancer of the endometrium was reported due to prolonged estrogen therapy without adequate rest periods.

Transplantation of Tumors.—We have seen that attempts to cause cancer with tumor tissue from man have failed. This does not mean that carcinoma cannot be transplanted from one portion of the body to another in individuals with this growth. Following the Mikulicz operation for carcinoma of the colon, cancer cells may be transplanted into the skin. Excessive handling of malignant tissue by the surgeon may actually transplant these cells. Recently a case was reported of transplantation from cancer of the breast to the donor site for skin graft on the opposite thigh which was taken at the time of radical mastectomy. Heterogeneous transplants have recently been done in animals by Greene and Saxon. These transplants survived and grew but they are essentially grafts which exist as parasites in the new host. They are not new tumors composed of cells derived from the host under the influence of a cancerigenic *agent carried by the tissue. The fact that tumors can be transplanted in series* in experimental animals demonstrates that malignancy is centered in the cells, since the new tumors resulting from the transplanted old ones are formed entirely by the multiplication of the introduced cells. But in spite of the intimate contact between the host's tissues and the tissue of the tumor for which it supplies blood vessels and supporting stroma, this does not lead to a malignant character change in the host's cells. In other words, the transplant is a graft and is limited by the same biological laws as those governing normal tissue grafting. Previously we spoke of natural resistance to cancer. This is not a resistance against cancer as a disease, as is the natural or acquired immunity againt tuberculosis or other diseases. It is the resistance against introduced cells of another individual of a different genetic make-up. In man this is evident in attempts at heterogenous, homogenous, or even isogenous skin grafts, even though whole organs such as a section of aorta have been successfully transplanted from man to man.

Transformation of Normal Cells Into Cancer Cells.—The transformation of normal cells into cancer cells lies within the cell partly at least in the cytoplasm, and the change is permanent and irreversible, making it possible for the cell to keep proliferating without any stimulus. This new property is a fixed character of the cell and is transmitted to all its descendants. Neoplastic change is not a mere exaggeration of chronic inflammation which it does resemble at the beginning. It is new, abnormal, and abrupt and is irreversible. Furthermore, it may not take place everywhere throughout normal tissue but here and there. When tumors appear on the basis of developmental anomalies they are said to be carcinogenic in that they provide a terrain suited to neoplastic change (von Recklinghausen's disease, intestinal polyposis).

In colon carcinoma a potentially malignant region exists prior to or coinci*dentally with the development of cancer. It is larger than the cancer itself* and its cause is unknown. There is an inflammatory reaction and the cells primarily concerned are mesoblastic which are the natural defense cells of the body. The effect on the epithelial cells is secondary and represents a stage of partial destruction or impairment of nutrition followed by a stage of attempted repair. The repair goes wrong (1) if a portion of the epithelium is isolated from the rest of the layer by a ring of lymphoid tissue as in polyp formation or (2) if epithelial cells become displaced into deeper parts of the submucous tissue as after ulceration.

Restraining Influence.—The factors governing the onset of malignancy seem to be not in the epithelial cells but in the mesenchymal cell system. Subepithelial connective tissue reacts with hyperemia and cells (leucocytes) followed by fibrosis, and this precedes

Cancer of the breast in mice involves three endogenous factors: (1) the genetic constitution or the hereditary susceptibility, (2) the presence of the female hormone estrone, and (3) the presence of the so-called mammary tumor inciter or "milk-factor." The latter is said to be present only in strains with a high incidence of spontaneous mammary cancer; it is absent in strains with a low incidence. Mice from a high cancer strain fostered by females from a low cancer strain have a lower breast cancer rate than litter mates nursed by their own mothers. The reverse is also true; that is, young from a low cancer strain fostered by females from a high strain have a higher mammary cancer rate. The tendency toward cancer of the breast is transmitted in greater intensity by the female than by the male; and factor (2), the presence of the estrogens as a cancer-producing agent, manifests itself more clearly in those strains with a high natural tendency; if the ovaries are removed at early sexual maturity, the rate drops almost to zero.

Since estrogens are partially detoxified in the liver and since thiamine is necessary for efficient liver function, low thiamine-high estrogen levels have been studied in uterine cancers. This combination is thought to be related to the cause of the disease.

Estrogenic hormones produce growth in the female genital organs. In normal animals after a brief period of activity there is retrogression, especially in the vagina and uterus and to some extent in the mammary glands. When the hormone is given in large doses continuously the genital organs do not regress and rest briefly after short phases of growth and function. Under such conditions it is possible to produce abnormal growths, atypical growths, and, in some cases, cancer. In monkeys a different effect may result; the uterus atrophies and the breasts keep growing. In cancer mice sexual cycles finally disappear and the vagina and uterus become atrophic and the ovaries small. If estrogens are injected, full growth of these organs returns, although the estrogens do not seem to affect the growth of the cancerous nodules. In male mice or low strain female mice (less than 5 per cent) large doses of estrogen may be carcinogenic.

Endocrine imbalance may cause spontaneous tumors; for instance, the secretion of estrogens by testicular tumors. The same condition has been found in dogs and also in mice; tumors or hypertrophy of the pituitary, ovaries, uterus, and mammary gland may affect each other. In mice transplanting the testes in females makes the pituitary enlarge which in turn stimulates the ovaries to produce a large quantity of hormone. Such mice develop cancer. This experiment refutes the charge that the dose and amount of hormone used experimentally in the production of cancer cannot be equaled by the animals' own production. However, this does not take into account the effect of antihormones or neutralizing factors which may be present in the body.

Estrogens affect tissues not primarily reproductive such as enlargement of the birth canal in certain animals, formation of new bone in marrow cavities, greatly increased phosphorus and calcium levels in birds. All effects can be reversed by the injection of male sex hormone. Testes will atrophy if estrogens are long continued in male mice.

Fibromyomas occur in guinea pigs after estrogen stimulation and not carcinoma—this is comparable to the rarity of carcinoma of the uterus in colored women and the prevalence of fibromyoma.

No cases of spontaneous cancer of the uterine cervix have been reported in mice—a few have occurred after estrogenic stimulation but the mice developed mammary cancer first—the genetic and tissue susceptibility are different. The mammary glands are most responsive to estrogens, then the epithelium of the vagina and cervix, and lastly the uterus and adnexa.

The highest incidence of carcinoma in the human female genital tract occurs at or after the menopause. Ovulation usually ceases after the menopause. This eliminates corpus luteum from periodically modifying or interrupting estrogenic stimulation which may still be present, resulting in an endocrine imbalance which may be conducive to

If any conclusion can be drawn from this review concerning the causes of cancer, it would be that progress is being made by clinical and experimental researchers. Our treatment at present is empirical because we have not broken down the barrier of causation. Cancer is probably a group of diseases very much like infections which represent a group of diseases, all evoking more or less similar tissue changes yet each one different, depending on various etiological agents. Moreover, one agent may produce more than one kind of cancer just as one type of microorganism may evoke various responses. It is, as in infections, probably the "potency" of the carcinogenic agent, the "ferocity" with which it acts, and the "defense" which the body is able to bring into play that determines the type and malignancy of the disease.

Nomenclature and Classification

The best way to classify tumors would be as we did with ulcers (see Chapter 6)—on an etiological basis. Obviously this cannot be done since in only a few instances is this possible with our present knowledge of the cause of new growths. The classification in the text is modified from Ewing and is based on the *histological* appearance. A histogenic classification would be better but this is not always possible. Such terms as neurofibroma, as distinguished from perineural fibroblastoma, is an attempt to show origin. When structure varies, histogenesis dominates the name—adamantinoma, hypernephroma, etc. We have used the word *blastoma* which means a true neoplasm of independent growth, usually of one embryonic layer and a predominance of adult cells. The word is derived from blastomere in which the cells are undifferentiated and hence blastoma is not a fully justified term used in its present connotation. Since adult tissues have various embryological derivations, we cannot classify according to germ layers such as ectodermal, entodermal, and mesodermal. Adami points out that there are two main tissues from early embryological processes which permanently retain their early characters; namely, lining membrane tissues, which he calls lepidic, meaning membrane, and pulp tissues or hylic, meaning crude matter. The former are composed of specific cells not penetrated by blood vessels and possess no stroma. The epiblast and hypoblast are primary and the mesothelium and endothelium secondary lepidic tissues. Hylic or pulp tissues are composed of cells separated by a homogeneous fibrillar stroma which may or may not be penetrated by blood vessels; the mesenchyme is of this type. Although oncology is not a part of embryology and anaplasia has little in common with the latter, yet it is of help in interpreting tumor growth, especially teratomas, and therefore the terms suggested by Adami are included in this classification.

The suffix *oma* means swelling; to indicate a particular growth it is preceded with the name of the tissue which makes up its main cellular structure. Tumors like normal tissue have various components. There is always the trunk and branches (blood vessels and connective tissue) and the leaves of flowers (epithelial elements) to every tree. So it is with tissue or organs. In a papilloma the significant component is the epithelial tissue

any alteration in epithelial cells. This resistance which checks the development of the initial malignant growth has been termed "primary resistance." While the cancer increases by autoplasty and spreads by metastasis, the rest of the area where malignancy may occur, which may be large, is not invaded by further or multicentric newgrowth due to "secondary resistance" caused by the presence of the initial cancer. If, however, the primary cancer is removed, then secondary cancer may be produced although it could not be induced as long as the primary growth was there. It may take six months in mice to get the secondary cancer to grow. This is equal to sixteen years in man. Is the removal of a cancer in man a check to autoplasty only? Then after the "secondary resistance" has ceased to act may a new cancer develop due to causes which *precipitated the first growth; that is, a second primary carcinoma?* This interesting speculation may explain five- or ten-year cures but the rarity of fifteen-year cures.

The restraining influence in cancer is, first, that of any foreign group of cells—an inflammatory reaction which tends to remove or destroy the invader and to localize such elements as cannot be eradicated. This is not a new phenomenon, for we have studied it in all types of injuries. It is clearly illustrated in the difference between *squamous-cell carcinoma and a special variety of malignant dermatosis or Bowen's disease.*

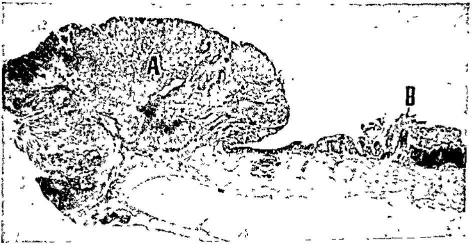

Fig 119.—Infiltrating carcinoma in Bowen's disease (low-power photomicrograph). Infiltrating carcinoma developing in an area of malignant dermatosis. *A.* Carcinoma arising in Bowen's disease which has penetrated into the underlying tissue. *B.* An adjacent area without penetration. Note the invasion of the stratum papillare of the skin in *A.*

Precancerous Conditions in Man.—With the advent of experimental cancer it became evident that even after a carcinogenic agent was applied much time elapsed before cancer resulted. During this time the tissue undergoes a pathological change which is not always apparent. In man most precancerous lesions have been noted on the skin (see Chapter 16). However, precancerous lesions have been noted elsewhere as in syphilis of the tongue, leucoplakia of the mouth, kraurosis vulvae. The precancerous conditions are not necessarily hyperplasia as in experimental skin cancer but may be epithelial atrophy. Atrophic lesions are radiation dermatitis, atrophic undescended testes, kraurosis vulvae, gastric ulcer, and chronic atrophic gastritis, although in the latter instance we are not sure whether it is cause or effect. Hyperplasia is more commonly a precursor as seen in gastric polyp, congenital polyposis of the colon, etc. More will be said of "precancerous lesions" in subsequent chapters. The term is equivocal because not in all cases are we sure of the forerunner of cancer and no sharp line of demarcation can be drawn between the precancerous and cancerous process. Perhaps precancerous lesions are carcinoma in situ if we could only find the cells.

even though there is a stalk with blood vessels and connective tissue; hence it is an epithelial neoplasm. Complex names such as fibroadenoma and fibromyoma are used to describe growths which are composed of more than one type of tissue. The prefix denotes the tissue which is present *in less amount: thus a fibroadenoma is an adenoma with some fibrous* tissue. They are simple mixed tumors. New growths with tissues or organs of one or all the embryonic layers are known as teratomas and are found usually in the ovary or testis. The plural of *-oma* is *-omas* or *-omata.*

Some terms which have been used for almost ninety years are probably not accurate. Myxoma is not a special type of new growth as listed below but is probably a connective tissue neoplasm which holds interstitial mucus. "Colloid" carcinoma is wrong because the substance is probably mucus and should be called mucous carcinoma. Other tumors which have recently been questioned are the adenomas which are thought by some to be hyperplasias and not true tumors and hemangiomas which in many instances are congenital anomalies, not neoplasms. Lastly, the term benign or innocent is always open to question. When is a true tumor innocent? Knowing the limitations of nomenclature permits us to set forth various terms which are currently used even though some are of historic interest only.

Classification (Histogenetic)

I. Epithelial neoplasms (lepidic)
- A. Benign
  1. Papilloma—a benign tumor of pavement epithelium with supporting tissue in normal arrangement
  2. Adenoma—a benign tumor of glandular epithelium with supporting tissue in normal arrangement
- B. Malignant

  Carcinoma (*carcinos*, crablike)

  Carcinomas may be further classified as follows:
  1. Consistency
     - a. Encephaloid or medullary—soft
     - b. Scirrhus—hard
  2. Type of epithelium
     - a. Simple epithelium
       - (1) Columner (in intestines, etc.)
       - (2) Cuboidal (in breast, etc.)
       - (3) Squamous (ear, Bowman's capsule, rete testes, and smallest excretory ducts of many glands)
       - (4) Transitional
     - b. Stratified epithelium
       - (1) *Squamous cell*
       - (2) Basal cell
       - (3) Combined
  3. Architecture
     - a. Adenocarcinoma, resembling glands
     - b. Carcinoma simplex, with a solid palisade of cells

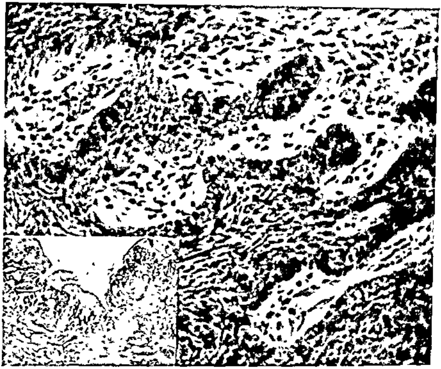

Fig. 120.—Basal-cell carcinoma (rodent ulcer) of the neck. The low power shows the ulcer and invasion of subcutaneous tissue The high power shows malignant cells, which originate from the *stratum germinativum* (Malpighian layer).

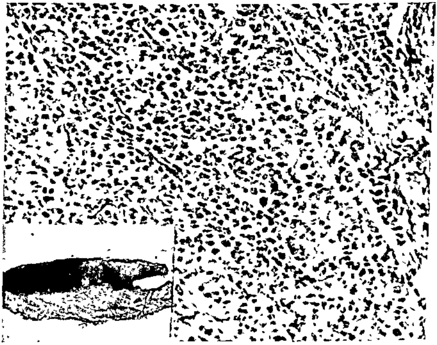

Fig. 121.—Malignant melanoma (from the arm). The low power shows the invasiveness of the tumor; the high power shows the lepidic arrangement of the cells. This has led to difference of opinion in classification, some naming the lesion melanosarcoma, others, melanocarcinoma. *The malignant cells are atypical in size, shape, and staining reaction.*

3. Nervous system (mesenchymal and epithelial parts)
    a. Glioma or neuroglioma—composed of neuroglia astrocytes, oligodendrocytes which are ectodermal and microglia which is mesodermal
    b. Neuroepithelioma—from neuro-epithelium
    c. Neuroma—nerve fibers and cells
    d. Neurolemmoma—Schwannoma or perineural fibroblastoma—neurolemma
4. Endothelioma—endothelium
    a. Angioendothelioma

B. Malignant
1. Sarcoma (*sarcos,* "meatlike"); are malignant tumors of connective tissue origin with cells and supporting tissue abnormal in morphology and arrangement
2. Immature forms—undifferentiated cells
3. Mature forms—more like normal cells
    a. Spindle cell sarcoma
    b. Round cell sarcoma
    c. Fibrosarcoma
    d. Chondrosarcoma, etc.

III. Mixed neoplasms

A. Simple mixed tumors—made up of more than one type of tumor tissue—benign-like fibroadenoma, malignant-like chondroepithelioma; adenosarcoma

B. Teratoma—monodermal, bidermal, or tridermal—tissues and organs of one, two, or three germinal layers

C. Embryoma—composed of tissues from three germinal layers in more or less orderly imitation of a fetus

D. Malignant
1. Sarcoma
2. Carcinoma
3. Sarcoma-carcinoides

General Observations Concerning New Growths

Incidence of Cancer.—Approximately 200,000 persons are expected to die of cancer in 1950. There are now between 600,000 and 1,000,000 people in the United States who know they have cancer. One of every 5 to 6 persons who die between the age of 45 and 70 years die of cancer. More people are living beyond 40—at present, 30 per cent. By 1980, 40 per cent of our population will be over 45 years of age—the cancer age group.

Cancer mortality by organ primarily affected as given by the 1942 United States Census showed 163,400 *cancer deaths. Table XII* shows a comparison between the figures of the United States Census Bureau in 1942 and figures from The National Cancer Conference in 1949.

This may not be entirely accurate because often the primary site is unknown—the metastatic area may be the only detectable region or organ involved.

1. A metastatic growth may overshadow the original if its environment is favorable. Example: Carcinoma of the sigmoid colon may grow slowly for years and then may metastasize to the liver and grow rapidly in this organ.

c. Carcinoma "in situ"—malignant cells have not as yet broken through surrounding tissues out of their parent epithelium

4. Function

Mucoid; since the epithelium functions in a rudimentary way, mucus may appear or there may be colloid degeneration; also called colloid, gelatinosum, or collonema.

5. According to histogenesis

a. Neuroepithelioma, composed of neuroepithelium

b. Choriocarcinoma, from chorionic epithelium

6. Reaction of tissues

Inflammatory carcinoma—vigorous tissue reaction with rapid spread

II. Mesenchymal and mesodermal (hylic) neoplasms

A. Benign

1. Connective tissue; are benign tumors of connective tissue origin, with supporting tissue in normal arrangement

a. Fibroma—fibrous connective tissue

b. Chondroma—cartilage

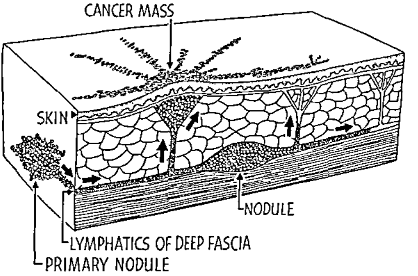

Fig. 122.—Diagram illustrating Handley's theory of permeation in carcinoma. The primary carcinoma is shown on the left. Cancer cells permeate along the tubular lymphatics on the deep fascia and then grow up the communicating vessels to the reticular lymphatics of the skin. A secondary nodule is indicated on the deep fascia, and the cancer mass seen in the skin is shown to have permeated also in all directions. A reaction takes place in the lymphatics (perilymphatic fibrosis), which results in their occlusion after the cells have permeated the area. In cancer of the breast this occlusion gives rise to edema (pigskin appearance *early*, and cancer en cuirasse *late*). Permeation is more rapid in the deep than in the superficial lymphatics; therefore, more fascia than skin should be removed. However, a wide area of skin is also involved, as shown.

c. Chordoma—chorda dorsalis (nucleus pulposus)

d. Osteoma—bone

e. Myxoma—mucous tissue (like Wharton's jelly)

f. Lipoma—fat tissue

g. Angioma—vessels

h. Hemangioma—blood vessels

i. Lymphangioma—lymph vessels

j. Lymphoma—lympoid tissue

2. Muscle tissue

a. Leiomyoma (smooth muscle)—mesenchymal

b. Rhabdomyoma (striped muscle)—mesodermal

prostate). *A third group include those organs not often affected by* primary or secondary growths (spleen, heart, skeletal muscle).

4. Tissue cells may be kept growing and reproducing for years in an artificial medium but they lose their power to differentiate into a particular kind of cell, such as epithelial, endothelial, muscle, etc. If connective tissue cells are added, they differentiate. *Cells devoting their whole energy to reproduction can do nothing else.* This may explain the dedifferentiation of rapidly growing, highly malignant neoplasms. Conversely, cells which exhibit a function (produce secretions, mucus excretions, bone) resembling their original duty are apt to be less malignant.

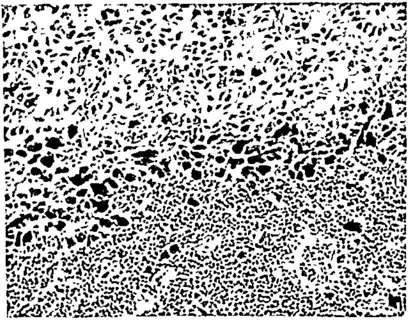

FIG. 123.—Lymph node showing metastatic melanoma. The growth metastasizes by the lymphatics (the nodes becoming dark in color) and by the blood stream (high power).

5. Certain cells may be inherited (in some people) which do not keep step with normal growth when a certain time in life is reached—instead, they grow wildly. This "certain time" may be hastened by deliberate exposure to carcinogens, exogenous and/or endogenous, and neglect of ulcerations or other precancerous changes.

6. Resistance: "The presence of large numbers of lymphocytes about the inoculated tumor and also about human malignant tumors makes it seem probable that these cells offer some special resistance to tumor growth." (MacCarty and Kehrer.)

We have seen that malignant tumors are known to have regressed and that the incidence of such growths is less in persons who have had severe infections such as erysipelas, peritonitis accompanied by high fever, and toxemia. It is now thought that this protection against tumors is due mainly to local tissue reactions. Illustrations of the efficient pro-

TABLE XII

	UNITED STATES CENSUS, 1942 (%)	NATIONAL CANCER CONFERENCE, 1949	
		MALE (%)	FEMALE (%)
Digestive organs and peritoneum	45.7	49.7	
Stomach	16.1	18	10.3
Large and small intestines	11.5	11.2	12.8
Bile tract and liver	6.3	5.4	6.4
Rectum and anus	5.4	6.4	4.6
Pancreas	3.5	4.4	3.2

Skin (except vulva, scrotum, and lip)	2.0	2.4	1.5
Brain and cord	1.6	2.1	1.4
Miscellaneous or unspecified	7.6	6.9	5.7

An example is the fact that metastasis, in primary melanotic sarcoma of the eye, is most frequent and attains greatest growth in the liver. This would seem to indicate that the liver tissues offer favorable conditions for the growth of this particular tumor. The frequency of the involvement of the liver in secondary tumor originating in the stomach is easily explained by anatomical relationship. Conversely, the spleen is an organ which rarely shows invasion by carcinoma. The spleen also frequently escapes even when there is widespread dissemination of sarcoma. This organ is richly vascularized and should be open to invasion by tumor cells floating in the blood stream. The spleen is frequently the seat of infarction, and it can therefore be assumed that foreign material floating in the blood stream is likely to be deposited there. Unless tumor emboli follow different physical laws of circulation and deposition than do other emboli, it would seem the spleen itself offers some *resistance* to the tumor growth. This may be due to the rich content of lymphoid cells in the spleen, since the studies of Murphy indicate that lymphocytes protect against tumor growth (Karsner).

2. The older organs in the phylogenetic scale are more resistant to carcinoma (small intestine, muscle), the younger less resistant (stomach, breast, rectum, uterus).

3. An organ not usually the seat of primary malignancy is often the site of metastasis (for example, the liver, bone marrow, lymph nodes). The reverse is also true; that is, organs commonly the seat of primary tumors are rarely the seat of metastasis (stomach, breast, pancreas,

action of estrogen. After pregnancy estrogen can act unopposed because progesterone is considerably diminished.

Our conclusions are as follows: (1) There is no proof that pregnancy starts a "latent" carcinoma into activity. (2) If carcinoma is present, the growth keeps pace with the proliferation of new cells (hyperplasia) and enlargement of old (hypertrophy). The environmental tissues and stimulated breasts are growing in size rapidly and

FIG 125.—Metastases to the tibia. Same case as shown in Fig. 124.

their resistance is high due to increased blood supply. The intrusion of malignant cells is resented and opposed by inflammatory changes—inflammatory carcinoma. (3) The trauma of birth and necessary repair may be a stimulus to cancer. (4) Involutional changes and transplantation of epithelial elements post partum may increase the rate of growth.

As a result of these concepts in carcinoma of cervix, (1) we have urged careful inspection of breasts and cervix during pregnancy and es-

tection against tumors by local tissue reactions are (1) local "immunity" conferred by light x-ray therapy against implantation of *experimental* cancer; (2) cure of certain cancers by local application of arsenic and other chemicals; although such diversified agents as potassium, arsenite, glycerine, Coley's fluid, carcinomatous glands, and solution of leucocytes may destroy malignant (not normal) cells, yet they all set up an inflammatory response which may be responsible for tumor regression; (3) transplanted mouse tumors may be cured by starch injection through *lymphocytic and different natural defense reaction in resistant animals;* (4) spontaneous recession or cure of malignant growths in patients by severe infection or inflammation; (5) partial or complete breakdown of tumors following the asphyxia produced by ligation.

Fig. 124.—Metastasis from malignant melanoma to the hypothalamic area of the brain. The original lesion was in the skin posterior to the ear. Arrow points to pigmented tumor mass.

Immunity cannot readily be induced in splenectomized animals and Murphy has found that the chick embryo will not resist implantation of tumors until the spleen and lymphocytes have appeared. Murphy *and* collaborators reduced the lymphoid tissue and the circulating lymphocytes *by employing the x-ray and found that there* was then a decreased resistance to tumor implantation. When they increased the number of lymphocytes in mice by the use of dry heat, they demonstrated a high degree of immunity to certain transplantable tumors.

7. Carcinoma and pregnancy: Carcinoma does not often occur during pregnancy *(1 to 2,476 labors—Danforth) probably* due to the fact that the disease is seen in an age usually past the reproductive period. We have seen it in the cervix and breast and have studied it carefully. Many observers state that carcinoma grows faster and metastasizes earlier in pregnancy. Others hold that cancer is slowed due to the fact that corpus luteum *hormone (progesterone)* checks the blastomogenic

Such symptoms and signs as *great loss of weight, anemia, generalized metastases,* the presence of a large ulcerative growth, severe pain, and cachexia occur in the *late stages* of malignant growths. Cachexia may be due to many factors, such as hemorrhage, interference with important functions (digestion, excretion, respiration, deglutition, etc.), secondary infection, and the absorption of toxic products from degenerated tissues. All may play a role in producing this ghastly picture.

The second method of diagnosis is by *x-ray* and the use of *endoscopy* (proctoscopy, cystoscopy, bronchoscopy, esophagoscopy, gastroscopy, etc.).

Fig. 127.—Primary bronchiogenic carcinoma of the lung. Note the extension of the growth beyond the bifurcation of the bronchus. The patient was a man aged 64 years who complained of chronic cough. A large metastatic nodule in the liver was palpable.

The third, and perhaps most important, method of diagnosis is *biopsy,* with careful study of the excised tissue under the microscope. Biopsy is not dangerous if properly done. This has been studied experimentally and clinically. In rats biopsies of transplanted adenocarcinoma does not affect the average survival period of the animals or increase the percentage with lymph node and lung metastasis. In man many writers have claimed that cautery biopsy actually forces cells into lymphatics, that instruments used in taking biopsy may transplant cells, in sarcoma malignant thrombi may break loose and be carried to the lungs in a

pecially if there is bleeding from the nipple or vagina. (2) In the early stages of pregnancy if cancer is proved and the patient willing, the pregnancy is disregarded and surgical and radiotherapy is used. (3) In the late stage of pregnancy—cesarean section with supravaginal hysterectomy and bilateral oophorectomy is performed, followed by radium and x-ray treatment to the cervix. In the breast we have done a radical mastectomy at once and followed it with x-ray therapy. In early pregnancy we have tried both hysterectomy with bilateral oophorectomy and x-ray which causes an abortion and stops ovarian function. The results were discouraging. In late pregnancy we have allowed the patient to go to term. Carcinoma and pregnancy is a highly malignant combination.

Fig. 126.—Adenocarcinoma of the stomach.

Diagnosis of New Growth

The diagnosis of a new growth depends first upon the *clinical manifestations.* These will be discussed in succeeding chapters under the systems in which they occur. Three clinical signs must be kept in mind in relation to cancer: (1) a lump or swelling in an organ; (2) a sore which does not heal readily; (3) an abnormal or bloody discharge or secretion from a gland or viscus. The following symptoms are equally important in connection with the foregoing signs: (1) absence of pain (in early stages) and (2) disturbance of function (indigestion in gastric carcinoma; constipation, or diarrhea, or alternation of these in carcinoma of the colon), overproduction of a hormone (pancreas) or production when normal function is over (theca-cell tumor of ovary), or perverted secretin (arrhenoblastoma), etc.

then staining or the material may be spread on a slide. The technique in general is fixation with equal parts of 95 per cent alcohol and ether and staining with hematoxylin and the O G 6 and E A 36 stains. (Papanicolaou.) See Chapter 2.

The fourth is *surgical exploration* where there is doubt. Diagnosis in the late stages is easy but is unavailing for treatment. In the late stages of malignancy, treatment is at best only palliative. In the early stages the surgeon may be in doubt during the operation. Frozen sections are made and they help to guide him.

Prognosis

The fate of a patient with carcinoma depends upon various factors but principally upon the degree of dissemination. If the growth is local it can be removed or irradiated with hope of a cure; if it has invaded adjoining tissue or lymph glands, it is less hopeful; and if it has spread to distant tissues, or lungs, it is hopeless. Another important consideration is the location of the growth—not only from the standpoint of early diagnosis, but from that of surgical extirpation as well. MacCarty has listed the following factors in the order of their importance:

1. The presence or absence of glandular involvement and distant metastasis.

2. Fixation of the growth, making its complete removal more difficult.

3. Location. If in a situation easily accessible to examination and treatment, early diagnosis and cure will follow. The reverse is true.

4 and 5. Renal and cardiac efficiency. Their role in cancer is similar to their role in general health. If poor, the prognosis is not good, for the therapeutic risk is greater.

6. Anemia, due to reduction in diet, to loss of blood, or perhaps, to toxemia. The greater the anemia, the greater the therapeutic risk. This may not affect prognosis if the anemia appears suddenly and is counteracted by transfusion.

7. Size of the growth. The larger the primary growth, the greater possibility of glandular involvement; hence, the worse the prognosis (although size alone may be misleading).

8. Age. The younger the patient, the worse the prognosis, all other factors being equal.

9. Direction of growth. Cancers which grow toward the lumen of an organ have a better prognosis than those which grow outward, invading its wall, for the latter are more apt to result in granular involvement.

10. Loss of weight may be due to the quality or quantity of the food, mechanical obstruction, pain, worry, infection, or to the absorption of toxins from disintegrating tissues It is important only in connection with other factors.

matter of seconds. These and many other objections have brought us to adopt the following procedure: (1) Biopsies are taken with a separate set of instruments; (2) the defect thus created is closed by inversion suture; (3) instruments, gloves, and gowns are discarded while waiting for report; (4) small growths are completely excised because if benign the operation is over; (5) large growths have permeation of lymphatics which in turn have a perilymphatic fibrosis close to the edge of the growth; therefore biopsies are taken from this edge because the center of the tumor may be necrotic and therefore noninforming; the edge shows active invasion; (6) sarcomas are usually seen in the extremities and wherever possible a proximal tourniquet is used which is not removed if sarcoma is present, amputation being done proximal to the tourniquet. In sarcomas of the shoulder this is not possible (see Chapter 21). Biopsies are cut by frozen section (for immediate study) or by

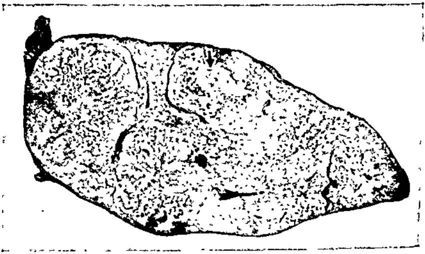

Fig. 128.—Metastatic areas in the liver in a patient with primary adenocarcinoma of the stomach. Woman aged 58 years. The specimen has been transected. The arrow points to one of three large nodules.

biconcave razor and stained with polychrome methylene blue (Terry's supravital technique). A study of biopsied tissue does not infallibly lead to the correct diagnosis and therefore all tissues excised are examined after paraffin blocks have been made and cut and special stains applied. However, the biopsy is an important aid in the diagnosis of new growths in the operating room.

Other aids to diagnosis are (1) the study of exfoliated cells from cancerous tissues by (a) vaginal smears in the diagnosis of uterine or vaginal carcinoma, (b) urethral smears and study of centrifuged urine in diagnosis of malignant neoplasms of the kidneys, ureters, and bladder, and prostate, (c) sputum smears and bronchoscopic washings in carcinoma of the respiratory tract, (d) gastric secretion obtained by aspirated fluid or through gastroscope, (e) exudates and transudates from pleural, peritoneal, and cerebrospinal fluid by making a "button" and

11, 12, 13, and 14. Cellular differentiation (the less differentiated, the more malignant); lymphocytic infiltration (prognosis better *with* than *without*); fibrosis (better with); and hyalinization (better with).

15. Duration of the disease. The history as to onset is often unreliable.

Treatment

If a growth can be completely removed, it is entirely curable. This statement holds true also if the related glands can be completely extirpated. It may be arbitrarily stated that the *best treatment is still radical and complete surgical excision.*

X-rays are useful in the preoperative control and aid postoperatively in the cure of cancer. It is perhaps true in some cases that x-rays used preoperatively seal the lymphatics and prevent dissemination, thereby increasing the efficacy of surgery. The postoperative irradiation, according to some, helps in the cure. Many groups of statistics seem to disprove this. This will be further considered under the various types of carcinoma, for radiosensitivity is an extremely variable factor and is useful in diagnosis as well as in treatment. (This is especially true of growths rich in immature cells, such as lymphosarcoma, Ewing's tumor, embryoma, etc.)

Radium has supplanted surgery in the treatment of certain lesions, such as carcinoma of the cervix and of the mouth. Coutard has shown that repeated small doses over a longer period of time are preferable to single large doses. Coley's mixed toxins are used in inoperable sarcoma. Repeated injections of *Bacillus prodigiosus and Streptococcus erysipelatis* may cause a disintegration of the growth with absorption. This may be explained by the reaction seen in the Arthus phenomenon. A great many nonoperative cures or recessions are associated with various inflammations. Many following incomplete surgery are due to asphyxia of the growth. Some recessions result from combinations of the above plus such chemicals as zinc and arsenic for reasons previously discussed. Lastly, a certain number of extensive carcinomas with incomplete surgery are helped by postoperative x-ray therapy because the induced (by surgery or infection) reaction is radiosensitive, whereas the original tumor may not have been.

Aids in the Treatment of Cancer.—

Androgens. Testosterone acetate and *proprionate* are useful in mammary carcinoma in women to relieve pain and delimit spread. The usual dose is 25 mg. every other day. Oophorectomy as an aid in treatment of breast cancer is doubtful.

Estrogens. Stilbestrol is very useful in the treatment of carcinoma of the prostate gland with or without metastases, causing a gain in weight, relief of pain, reduction in size of enlarged nodes and of the prostate. Serum acid phosphatase levels are decreased. The dose is 5 to 10 mg. daily. Orchiectomy is very helpful.

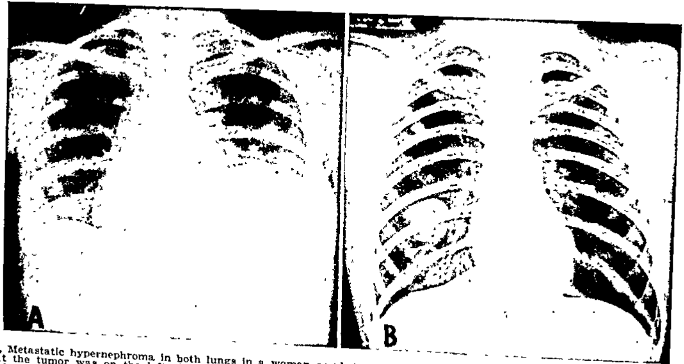

Fig. 129.—*A*, Metastatic hypernephroma in both lungs in a woman aged 41 years. There is elevation of the left leaf of the diaphragm due to the fact that the tumor was on the left side. *B*, Pulmonary metastasis from fibrosarcoma of the leg. Single metastases of this type may be treated by lobectomy after the primary lesion has been removed. We have removed a lobe of the lung in metastases from hypernephroma, fibrosarcoma of the leg, adenocarcinoma of the sigmoid. All patients recovered but ultimately succumbed to the disease except the last. This woman is alive and without recurrence three years after lobectomy and seven years after the colon resection.

Fig. 131.—*A*, Metastatic lesions of the pelvis, femur, and spine, due to cancer of the breast. These may be single or multiple and may show destruction, or (rarely) local areas of increased density. *B*, Metastatic nodules in the pelvis due to carcinoma of the prostate. The iliac crests are not shown; they presented a typical moth-eaten appearance.

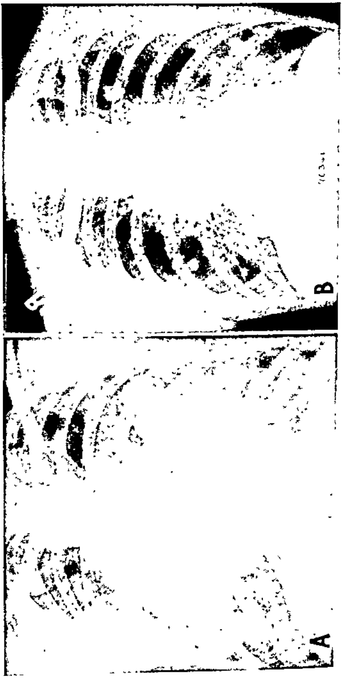

Fig. 130.—*A*. Extensive metastases to the lungs from teratoma of the testis. *B*. Metastases to the lungs from carcinoma of the breast.

obstruction is sudden but far removed from the organ (as low in the ureter), then all of the organ will not be involved at the same time and moreover some parts of it will derive a blood supply through collateral circulation and instead of atrophy there will be dilatation of the proximal parts of the ducts with cyst formation due to distention and pressure atrophy immediately around the dilated duct. Examples of this are seen in hydronephrosis especially from vesicle neck obstruction due to prostatic hypertrophy or ureteral stone and in carcinoma of the head

Fig 132—Thyroglossal duct cyst. The cavity was injected with methylene blue and excised.

of the pancreas with distended gall bladder which dilates before intrahepatic duct dilation occurs. Even the stomach becomes enormously dilated with resulting thin walls from intermittent complete obstruction as seen in ulcer or polyp. Partial obstruction usually leads to hypertrophy in all examples given. It is the muscular elements which are responsible because these force the secretions out through the constricted but not occluded duct.

Infection may alter any effect of obstruction, having its characteristic destructive action leading to infected hydronephrosis, thick-

Isotopes. Radiophosphorus has been used in leucemia, lymphosarcoma, polycythemia vera, myeloma, Hodgkin's disease, and metastatic carcinoma. Results are doubtful. Given orally the dose is usually 1 to 2 millicuries per week for several weeks. As much as 100 millicuries per kilogram of body weight have been used as the total dose. *Radioactive iodine* has been used with encouraging results in carcinoma of the thyroid and in metastatic carcinoma of the thyroid. Other isotopes are radioactive iron, sodium, potassium, chlorine, bromine, calcium, strontium, sulfur, carbon, and hydrogen.

Nitrogen mustard methyl bis (2-chlorethyl) amine hydrochloride has been used in daily dose of 0.1 mg. per kilogram of body weight given intravenously for the control of lymphoblastic diseases. Results have been equivocal.

Stilbamidine (4,4′-stilbenedicarboxamidine), ethylstibamine (Neostibosan) and *urethane* has been tried in leucemia and metastatic carcinomas. Stilbamidine ethyl carbamide is given orally, intravenously, or intramuscularly daily in doses of 0.5 to 2 Gm. There have been reports indicating relief of pain.

Other chemical agents which should be mentioned as still in the early experimental stage are *Serratia marcescens (Bacillus prodigiosus)* polysaccharide; KR (carcinolytic substance of *Trypanosoma cruzi*, named after Klyueva and Roskin); antireticular cytoxic serum (ACS); folic acid antagonists such as aminopterin (4-amino-pteroylglutamic acid) and amino-an-fol (4-amino-pteroylaspartic acid).

CYSTS

A *cyst* is a swelling consisting of a wall and fluid or semifluid contents. It usually results from the distention of pre-existing ducts or spaces, or from new growth.

Cohnheim studied the effects of complete obstruction of the principal duct of a secreting gland. This usually produces atrophy of the organ. The retained secretion or excretion increases under pressure (glands will secrete or excrete against a pressure gradient) which finally equals the venous pressure of the organ. When venous pressure finally equals arterial pressure, cellular degeneration and necrosis results from asphyxia; then there is absorption through surrounding lymph and blood capillaries of tissue debris, with final fibrosis and atrophy. Examples of this are seen in kidney atrophy and fibrosis after sudden and complete ligation of the ureter and in liver atrophy and cirrhosis after accidental ligation and division of the common bile duct. Obviously the first effect is an increase in size of the organ due to retained products and passive congestion; the end stage is atrophy.

These effects are variable depending on other factors, principally infection and pressure gradients. The latter will be considered first. If the principal duct is slowly and/or intermittently obstructed or if the

2. Epidermoid cysts. Surrounded by squamous epithelium with smooth walls or pearly granules containing clear fluid.

3. Blood cysts (hematoma). May be due to endometrial transplants.

4. Cysts due to foreign bodies which become encapsulated; also parasitic cysts, as echinococcus cysts.

5. Cystadenoma. The proliferating papillary cystadenomas have malignant tendencies in the ovary and breast.

6. Cystic degeneration may occur in any new growth.

7. Transplantation cysts. Due to epithelial transplants at operation or from injury. (Acquired dermoid or epidermoid cyst; also cystadenomas may be transplanted at operation into peritoneal cavity and vagina in panhysterectomy; endometrial transplants at operation or spontaneous.)

8. Inflammatory cysts. Result from an infection untreated with destruction of cells and abscess formation. Liquefaction of pus and filling of dead space with serum surrounded by scar. The wall is scar tissue.

Diagnosis

The diagnosis of a cyst is made from its transmission of light, its fluctuant quality, and its position. In case of internal cysts, a sense of resiliency is palpated, and the position (usually ovary) makes the diagnosis possible.

Treatment

Retention cysts are treated by excision of the cyst wall so that they may not re-form. Sometimes cysts are cured by the injection of sclerosing agents or spontaneously due to infection and inflammation.

Where the cyst involves an ovary, the ovary is usually removed (except in the case of a follicular cyst) because many cysts are new growths and may lead to malignancy. Endometrial cysts are treated by excision. If many transplants are present (endometriosis), ovarian function is destroyed by x-ray or surgical castration.

In the case of cysts due to parasites, the cyst wall and the daughter cyst must be carefully removed if that is possible; if not it is chemically destroyed. This is a rare state.

In general, the treatment of a cyst is the removal or extirpation of the cyst wall. This is usually feasible. In hydrocele, the tunica vaginalis is simply everted. Sometimes the wall of a cyst is marsupialized (as in mediastinal dermoids and pancreatic cysts) although here extirpation is preferable if possible. In extravasations into pre-existing cavities, aspiration is sufficient, because the wall of the normal cavity will assume its power of secretion and absorption when the disease process causing it ameliorates (pleurisy with effusion, hematocele, hematocolpos, etc.).

In this chapter we have discussed, in a general way, the subject of tumors and cysts. It remains now to review the manifestations of these growths in their respective organs and tissues and finally to describe their treatment. This will be done in succeeding chapters.

ening and decrease in size of the gall bladder from common duct stone, etc. Conversely, obstruction to an excretory duct is perhaps the most important *cause of infection in an organ.*

Classification of Cysts

Distension Cysts.—

1. Retention cysts *(congenital or acquired) are due to obstruction of* the duct of a gland and may occur in sebaceous glands (wens), the salivary glands (ranula), the breast, the pancreas, the kidneys, etc.

Fig. 133.—Dermoid cyst. This is a common site. The cyst was excised.

2. Exudation cysts are due to an accumulation of fluid in a pre-existing cavity *(ganglion of tendon, hydrocele, etc.).*

3. Extravasation cysts are due to hemorrhage in a pre-existing cavity (hematocele cysts, etc.).

4. Congenital cysts are due to anomalies of the lymph spaces or to failure of an embryonic cavity to close *(cystic hygroma of the neck* [lymph], branchial cleft cysts, thyroglossal duct cysts, mesenteric cysts, etc.).

Cysts of New Formation.—

1. Dermoid cysts (in skin, ovary, testes). May contain *epidermis,* dermis, and dermal *glands.*

PART V

DISEASES AND INJURIES OF SPECIFIC ORGANS AND SYSTEMS

In foregoing chapters we have outlined the general principles involved in the causation and response to injury. In the remaining chapters of the book we shall consider these principles as applied to particular organs and systems.

It is difficult to follow a definite outline in all instances. However, a convenient method of presentation includes the following studies: (1) Embryology, (2) Anatomy (Gross and Microscopic), (3) Physiology, (4) Abnormalities. The latter may be considered under the following heads: I. Functional disorders, which may be motor, sensory, secretory, circulatory, excretory, or combinations. II. Organic changes due to (a) Congenital malformations, (b) Traumatic injury, (c) Infections and inflammations, (d) Neoplasms, (e) Miscellaneous causes including diminished or increased blood supply, obstruction to principal duct from various causes, calculi, etc. III. Combinations, functional derangements leading to organic changes (such as Raynaud's disease, tumors of endocrines, etc.), the reverse of which is usually the case. *Wherever possible the disease will be presented under the following* heads: etiology, pathology, symptoms and signs, diagnosis, prognosis, and treatment.

Lastly, where surgical operations are indicated, a brief discussion of preoperative preparations, operative technique, and postoperative care will be considered as applied to specific procedures.

baceous material, and, as we have seen, it plays an important role (in man) in the regulation of the body temperature, the water balance, and chloride metabolism. It is provided with numerous accessory organs such as hair, nails, sebaceous glands, and sweat glands. Hair is present in at least a rudimentary form over the entire body except on the flexor surfaces of the hands and feet, the dorsal surfaces of the terminal phalanges, the glans penis, the inner surface of the prepuce, and the medial surfaces of the labia. Sebaceous glands occur with the rudimentary hair follicles, and therefore areas which are devoid of external hair may have boils, carbuncles, and sebaceous cysts. This does not apply to the regions mentioned that are entirely without even the rudimentary follicle (the lanugo of the fetus). The dog has few sweat glands; consequently he must regulate body temperature and fluid loss through the respiration, the kidneys, and the bowel.

Immunity

Koch's rapid strides in bacteriology influenced many of his time to believe that "the individual has no more resistance to bacteria than a soldier to bullets." However, Ehrlich clearly demonstrated that there are humoral substances which he called antibodies to fight bacteria and their toxins (agglutinins, precipitins, antitoxins, bacteriolysins, alexins, opsonins, hemolysins, etc.). Later, Metchnikoff showed the value of phagocytic cells in local immunity (macrophages, reticulo-endothelial cells, etc.). Today we believe that both play an important role, with perhaps local immunity the more important of the two.

The skin possesses a high degree of *immunity*. This must be true since it is in contact with bacteria at all times. We have seen that even after careful surgical preparation the skin harbors bacteria in the hair follicles, sebaceous and sweat glands, horny fat, crypts, and crevices. Recent studies seem to show that bacteria are found in most tissues of the body. They are not always pathogenic for experimental animals unless they are incubated. It is important to know these facts since the entire problem of skin infection hinges upon it. If the skin is not devitalized by trauma or strong chemicals, and if the general condition of the patient is good, infections will not occur when reasonable cleanliness is exercised. Resident bacteria are mostly *Staphylococcus albus*. They cannot be entirely removed by scrubbing or strong antiseptics. In fact, preoperative scrubbing done the night before surgery increases the flora which becomes less after five to six days. Therefore we do not scrub the operative field the night before surgery.

Inflammatory reaction in the skin is in the dermis and hypodermis rather than in the epithelial cells which apparently have no defensive or phagocytic powers. They respond to irritation by degeneration or disintegration, as in hyperkeratosis or leucoplakia, or by hypertrophy and hyperplasia, as in condyloma formation. In early carcinoma the

CHAPTER 16

THE INTEGUMENTARY SYSTEM AND ADIPOSE TISSUE—SKIN, NAILS, HAIR; SEBACEOUS GLANDS, SWEAT GLANDS, MAMMARY GLANDS

INTEGUMENTARY SYSTEM

The skin forms a covering over the entire body and in a modified form, as mucous membrane, lines the body cavities. It is ectodermal in origin (see Chapter 3 for embryological considerations) and histologically is called stratified squamous epithelium.

The skin is composed of two layers. The outer layer is known as the epidermis and the under layer as the derma or corium. The former is composed of (a) the stratum corneum, (b) the stratum lucidum, (c) the stratum granulosum, and (d) the stratum germinativum (Malpighian layer). The derma or corium is composed of (a) the stratum papillare and (b) the stratum reticulare. The skin also contains sweat and sebaceous glands (which connect with the outside) and hair follicles. Elastic fibers roughly follow these hair pits. The hypodermis is subcutaneous tissue.

The normal integument is covered with valleys (sulci) and ridges (cristae). In a rough way these show the lines of the elastic fibers. If wounds occur or incisions are made parallel with these fibers, the scar will be narrow, with minimal deformity, whereas if they cut across the fibers there will be separation of the wound margin and increased scar formation (see Chapter 3). The most important layer of the epidermis is the lowermost (the stratum germinativum) for it is chiefly from this layer that new cells are made. Consequently, if in burns or wounds this layer is destroyed, a scar is sure to form (see Chapter 6).

Blood and lymph vessels are carried in loose connective tissue into the stratum papillare and from here they penetrate the lower layers of the epidermis as far out as the stratum granulosum. The capillaries are seen as small loops, and the lymph vessels end as small blind sacs, forming a meshwork comparable to a layer of mesh gauze in the epidermis. These lymphatics are known as the reticular lymphatics and they in turn go down connective tissue columns to empty into the large lymph vessels which lie on the deep fascia (tubular lymphatics), which in turn empty into anatomically related lymph nodes. Such infections as erysipelas and tubular lymphangitis involve these structures.

The skin protects the organism from injurious external influences, it receives sensory impulses from the outside, it excretes water, salt, se-

lent from the start (that is, full of polymorphonuclear leucocytes). In both infection and injury the forces of repair are at work. However, they cannot succeed until local immunity is established. This is true because the toxins destroy granulation tissue as fast as it may be formed. Therefore, immunity and inflammation are not the same thing, and although inflammation is necessary to secure repair, the former does not guarantee the latter.

Repair is said to occur by *first intention (per primam)* if a minimum amount of granulation tissue is necessary. A clean cut made by a sharp instrument produces a minimum of trauma and if not accompanied by infection heals by first intention. At first blood from the capillaries and arterioles exudes in the wound. In about four or five minutes this clots. Fibrin is deposited and forms a "scaffold" for the exudate (plasma) which begins to be poured out within thirty to forty minutes. Therefore, there is swelling. Microscopically, this exudate is seen to contain blood plasma, macrophages, polymorphonuclears, some lymphocytes, endothelial cells, and later (about the fourth day) fibroblasts which become fibrocytes. The activities of these cells are to (1) fight invading organisms which are always present; (2) remove debris (macrophages, reticulo-endothelial cells, histiocytes, pericytes); (3) form capillary loops (endothelial cells); and (4) form collagen from which connective tissue ultimately develops (fibro blasts). The polymorphonuclears come from the blood stream, the macro phages from the blood stream and tissues (tissue wandering cells), the endothelial cells from the cut ends of capillaries and perhaps from histiocytes, and the fibroblasts from tissue spaces or histiocytes. The endothelial cells form in rows, which later become canalized. The entire mass of soft purple tissue is known as granulation tissue. It is a living structure, filled with immune bodies and capable of repairing a defect. On the surface of the incision the plasma has formed a crust. This is impermeable and distinctly bactericidal and is a better dressing than the surgeon could make. Under this crust the epithelial cells creep across on the granulation tissue covering the defect. Later the connective tissue contracts, squeezing blood out of the now useless capillaries and the scar contracts. The repair tissue is sufficiently strong to withstand slight tension within seven days and in two weeks is fairly firm. After six months the scar is bleached and contraction has occurred in each direction. In healing by first intention contraction is minimal (Chapter 3).

Healing by second intention requires the same forces. However, this type usually follows infection or denudation of a large area. Much granulation tissue is required and after immunity is established this fills the defect (healing from the bottom up). If excessive, it is commonly known as "proud flesh." As soon as this is accomplished, epithelial cells begin to grow in from the epithelial border of the wound. They are seen grossly as a delicate gray membrane. If the defect is not too large, they will ultimately cover the area. (This border should not be irritated or

hyperplasia is a disorderly attempt to repair damage to cells. In inflammation the skin does retain water and if slightly irritated protects itself in part by blister formation (see Chapter 6—Thermal Injuries).

In all *infections* there are two factors to be considered: (1) the invading organisms, and (2) the resistance of the host. Although the skin is contaminated at all times, infection does not occur unless the defense mechanism is impaired. The mere presence of bacteria does not constitute an infection. When infection occurs, nature clearly shows us by pathological and clinical signs: locally, by hyperemia and exudation (which are manifested *clinically* by heat, redness, swelling, and pain); and *systemically*, by fever and leucocytosis.

Usually ordinary street wounds are contaminated by various strains of bacteria. They are not present in large numbers if the wound has been unmolested. Should infection result, in most instances it will be due to a mixed infection, and therefore clinical signs and symptoms will not be true to any particular type. The site of the injury may play a role, for example: oral, usually mixed streptococcus and staphylococcus; abdominal, the intestinal flora, etc. This indicates that often the infection which may result is endogenous. As a rule, however, there are three chief kinds of infection seen after accidents. First, there are those caused by skin staphylococci (*Staphylococcus pyogenes aureus* and *Staphylococcus albus*) and giving rise to a localized type of inflammation. Second, there are those induced by streptococci (*Streptococcus pyogenes* and *Streptococcus hemolyticus*), a more serious type which gives rise to a spreading or diffuse type of inflammation (phlegmon). Lastly, there are infections by the anaerobic group, *Clostridium perfringens* (*Bacillus aerogenes capsulatus*) and sporogenes (*Bacillus edematis maligni*) and *Clostridium tetani* (*Bacillus tetani*). These are very serious and occur usually in punctured or badly devitalized wounds where oxygen is absent. The formation of gas and the wide destruction of tissue have given rise to the name gas gangrene. Not all collections of gas in the tissues are due to the Welch bacillus. Anaerobic bacteria normally inhabit muscle. They are nonpathogenic. Gas in the tissues without marked symptoms is seen after simple fracture, contusions, and injections of adrenalin in doses sufficient to produce local devitalization. Careful observation of clinical symptoms and signs is necessary to differentiate this from the more severe types. The indigenous anaerobes may become pathogenic in the presence of streptococci. After destruction of the skin, either by trauma or infection, nature attempts to heal or repair the defect. As we have seen, inflammation is nature's way of mobilizing its immunizing forces to combat infection or injury. In infection, these forces are chiefly concerned with fighting the invading organism until it is annihilated or (what is perhaps a truer statement) of making the tissues at the site of invasion (and if necessary, the body as a whole) an unfavorable place for bacteria to grow. The exudate in this case is puru-

lent from the start (that is, full of polymorphonuclear leucocytes). In both infection and injury the forces of repair are at work. However, they cannot succeed until local immunity is established. This is true because the toxins destroy granulation tissue as fast as it may be formed. Therefore, immunity and inflammation are not the same thing, and although inflammation is necessary to secure repair, the former does not guarantee the latter.

Repair is said to occur by *first intention (per primam)* if a minimum amount of granulation tissue is necessary. A clean cut made by a sharp instrument produces a minimum of trauma and if not accompanied by infection heals by first intention. At first blood from the capillaries and arterioles exudes in the wound. In about four or five minutes this clots. Fibrin is deposited and forms a "scaffold" for the exudate (plasma) which begins to be poured out within thirty to forty minutes. Therefore, there is swelling. Microscopically, this exudate is seen to contain blood plasma, macrophages, polymorphonuclears, some lymphocytes, endothelial cells, and later (about the fourth day) fibroblasts which become fibrocytes. The activities of these cells are to (1) fight invading organisms which are always present; (2) remove debris (macrophages, reticulo-endothelial cells, histiocytes, pericytes); (3) form capillary loops (endothelial cells); and (4) form collagen from which connective tissue ultimately develops (fibro blasts). The polymorphonuclears come from the blood stream, the macro phages from the blood stream and tissues (tissue wandering cells), the endothelial cells from the cut ends of capillaries and perhaps from histiocytes, and the fibroblasts from tissue spaces or histiocytes. The endothelial cells form in rows, which later become canalized. The entire mass of soft purple tissue is known as granulation tissue. It is a living structure, filled with immune bodies and capable of repairing a defect. On the surface of the incision the plasma has formed a crust. This is impermeable and distinctly bactericidal and is a better dressing than the surgeon could make. Under this crust the epithelial cells creep across on the granulation tissue covering the defect. Later the connective tissue contracts, squeezing blood out of the now useless capillaries and the scar contracts. The repair tissue is sufficiently strong to withstand slight tension within seven days and in two weeks is fairly firm. After six months the scar is bleached and contraction has occurred in each direction. In healing by first intention contraction is minimal (Chapter 3).

Healing by second intention requires the same forces. However, this type usually follows infection or denudation of a large area. Much granulation tissue is required and after immunity is established this fills the defect (healing from the bottom up). If excessive, it is commonly known as "proud flesh." As soon as this is accomplished, epithelial cells begin to grow in from the epithelial border of the wound. They are seen grossly as a delicate gray membrane. If the defect is not too large, they will ultimately cover the area. (This border should not be irritated or

destroyed with silver nitrate, as is sometimes done.) The more granulation tissue, the more connective tissue and the greater the contraction; therefore, the more noticeable and deforming the scar.

So-called *healing by third intention* implies the union of two surfaces covered by granulation tissue which are brought together by sutures (delayed or secondary closure) or adhesive after local immunity has been established. This was first practiced during World War I (1914-1918). It is a useful way of shortening healing time and was used in World War II purposefully in badly contaminated wounds.

Traumatic Injuries

A *wound* implies a break in continuity of the skin which may be microscopic in size. However, as has been shown in Chapter 14—Shock, trauma may be applied in such a way that the skin is unbroken, yet severe hemorrhage may occur beneath it. There may even be rupture of a solid or hollow viscus without any sign of skin injury. Therefore, every contusion to any part of the body deserves careful study.

Wounds may be produced by a mechanical force, by thermal agents (heat or cold), by chemicals, by electrical discharges, and by x-ray or radium (Chapter 6). Those produced by mechanical forces may be divided into the following:

1. *Incised* wounds are those which are inflicted by a cutting edge such as a piece of glass or a knife. It is the kind that we produce in surgery. It heals most readily. It will probably remain uninfected longer than any other type of wound. It often heals by first intention if let alone and put at rest. Conversely if traumatized by strong antiseptics or rough surgery under the guise of débridement it may be converted into a contused wound. The eight-hour period within which a wound may be sterilized will vary with the kind of wound. Very few *wounds are primarily contaminated.*

2. A *contused* wound is one that is produced by blunt force. Sometimes there is sufficient trauma to destroy the skin; usually there is a break in continuity of the skin. It does not heal as readily as an incised wound because the tissue around the wound is devitalized.

3. A *lacerated* wound is one due to a tearing force. This heals slowly but not as slowly as the devitalized wound. Surgeons will often trim the frayed edge which is mostly dead tissue (débridement), thus converting it into an incised wound.

4. A *punctured* wound is one that is produced by a sharp-pointed instrument. Such a wound is the result of a needle, or a nail, or a stab wound produced by a knife. It has one great danger. It seals itself, producing an anaerobic medium favorable to the growth of *Clostridium perfringens, sporogenes* and *tetani.*

5. *Gunshot* wounds are punctured wounds produced by a bullet or shot. The bullet often carries pieces of clothing, etc., into the wound.

High velocity projectiles do not usually carry foreign material into wounds. However, this is unpredictable and therefore such wounds are carefully explored and débrided if necessary.

6. A *brush* burn is a superficial denudation of the skin.

The *presence* of a wound does not constitute an infection. If the area about the wound is thoroughly cleansed with soap and water for five minutes, using soft cotton, and if the wound is irrigated with copious amounts of physiological saline, infection is unlikely, provided this cleaning is done within six to eight hours from the time of injury. Soap solution is not a strong germicide but the mechanical scrubbing removes most of the transient flora of bacteria from the skin if continued for eight to ten minutes. Soap does not irritate the wound if it is washed out. It does aid in the removal of small foreign bodies, particles of dead tissue, and blood clot. Soap solution is weakest against staphylococci. Suturing *of skin wounds may be indicated if the injured tissue can be rendered* relatively free from bacteria; it is not indicated in wounds over ten hours old and may actually delay healing, except on the face, where the blood supply is excellent and local immunity is high. In badly contaminated or infected wounds delayed closure (five to six days) is preferable.

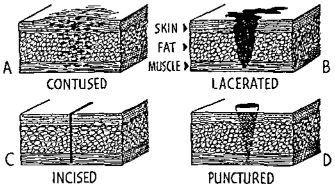

FIG. 134.—Diagram illustrating types of wounds. *A*. Contused wound produced by blunt force. There is great destruction of tissue. *B*. Lacerated wound produced by a tearing force. This results in an irregular wound with greatly damaged margins. *C*. *Incised wound produced by a sharp instrument.* *This* produces a minimum of trauma to tissue and healthy edges. *D*. Punctured wound produced by a sharp instrument. This seals itself quickly with serum and results in an excellent environment for anaerobic organisms.

As we have already seen, the less destruction of tissue, the less the possibility of infection, the smaller the area to heal, and, therefore, the more likely repair by first intention.

Obviously, then, an incised wound should heal better than a contused or lacerated one; that is, more quickly and with less scar. Punctured, gunshot, and stab wounds are dangerous because the wound is small and deep: it soon seals over, producing an anaerobic medium which is excellent for the growth of the *Clostridium perfringens, sporogenes* and *tetani*, and anaerobic streptococci. Brush burns are so very common that something must be said of their treatment.

Treatment of Wounds Produced by Mechanical Force.—*Arrest hemorrhage first.* This may be done by a tourniquet or by a tight bandage. If it is an extensive wound, the patient should be removed to a hospital. The wound is covered with sterile gauze and bandaged tightly. If an elastic bandage is available, it is applied. Many wounds which are relatively clean are contaminated by the first-aid attendant. Such contamination may be due to unclean hands, bacteria from nose and throat, washing the wound and surrounding tissue in such a manner that dirty water enters the wound, strong antiseptics, and rough handling. First-aid workers should be taught to cover the wound with a large amount of sterile gauze, bandage the part, and apply a temporary splint.

Then treat the patient as a whole for shock. This has been discussed in Chapter 14. However, a diagnosis as to the extent of the injury, the patient's general condition, and the presence of multiple injuries must now be made. Our experience in civil life has been the triple combination of head injury, abdominal or thoracic internal injury, and superficial skin wounds. In industry the hands are injured most. Lastly, one must be on guard for an injury in an individual who has had diabetes, a stroke, etc. When reaction has occurred, the wound should be treated. Let us assume that it is a lacerated and contused wound, filled with grease and dirt. The indications are clear and may be categorically stated as follows: (1) Control the hemorrhage by placing clamps on bleeders or leaving the tourniquet in place; (2) scrub thoroughly; this removes contamination and enables the surgeon to (3) make a careful inspection; (4) surgically remove any dead or devitalized tissue (débridement); (5) ligate the vessels and repair the nerve, muscles, tendons, and skin.

By *repair* we mean the restoration of continuity. This does not always mean functional restoration but may be only anatomic. Nor does it imply that repair will be made by like tissue. In general, the more highly specialized a tissue, the less its ability to regenerate itself. Of the five primary tissues, nervous tissue is perhaps most highly developed. Therefore, although the neurilemma of a nerve *fiber* may heal and the axis cylinder may grow down its sheath of Schwann if myelin is present, the cell *body,* if destroyed, will not regenerate itself. We have all the nerve cells we are going to acquire at birth; these may develop but will not increase in number nor regenerate when destroyed. Muscle tissue is also highly specialized and when it is destroyed repair takes place not by muscle but by connective tissue. Therefore, in sewing muscle, small amounts are included in the loosely tied sutures. Vascular tissue is partially able to regenerate. Epithelial tissue likewise is not entirely able to regenerate, for after the skin has healed there is an absence of sebaceous glands, sweat glands, and hair follicles in the scar. Connective tissue, the least specialized, is completely able to regenerate itself. (This includes tendon, bone, and cartilage.)

Various tissues contain special local characteristics which help healing. Local immunity is high about the anus and vagina and in the mouth. Therefore, although infection may occur, it does not greatly delay healing. The mesothelial tissues (pleura and peritoneum) heal very quickly (protective exudate composed of plasma fibrin is present within thirty minutes after an injury). The blood supply is also an extremely important factor in healing.

Perhaps the greatest factor in repair is the presence of normal, healthy cells. Anything devitalizing these will delay the process. However, there are other important factors: (1) *Infection.* This causes destruction of a wide area of tissue which is only healed after immunity is established, and then by second intention. (2) *Foreign bodies.* These must be removed. Grease, cinders, blood clots, wood, glass, hair, etc., are frequently closed within a wound. If a surgeon wishes to delay healing in part or in toto he introduces a packing or drainage tube. (3) *Blood supply.* The better the active exchange of oxygen and carbon dioxide and the more adequate the nutrition, the better the wound will heal. These processes are accomplished by an active blood supply. Sutures tied *snugly will produce anemia of the wound: allowance should be made* for swelling, which soon occurs. Tight bandages and casts are objectionable because they cut off the circulation. If the vessels are sclerosed (due to arteriosclerosis, thromboangiitis obliterans, or Raynaud's disease) healing will be delayed. At a site of complete occlusion healing may be impossible and there will be ulcer or gangrene. Stasis of blood may also retard healing. Asphyxia plus stasis may produce death of tissue. This is a result of occlusion of the venous return and is seen at its worst in Volkmann's contracture. In varicose veins there is stasis, accumulation of metabolites, insufficient oxygenation, and edema of tissue. Wounds do not heal in this environment. In the lower leg an elastic bandage with sponge pressure facilitates healing, especially in the presence of varicosities. (4) *Rest to the part.* A wound must be at rest to heal by first intention. This is the purpose of suturing the skin and of applying a cast in a fracture. Constant motion destroys granulation tissue and impedes its formation or leads to excess formation, thereby delaying repair; however, there is a possibility of the margins being too immobile. An extremity, for example, may be so thoroughly immobilized that circulation may be impeded. The stimulus of a very slight degree of motion may be important in bone repair. (5) The *size of the wound* may influence repair. Large denuded areas may be entirely healthy but the area may be too large for epithelization. This is seen after burns. Even if healing could occur it would be unwise to permit it. A vicious cicatrix would form, producing a crippling deformity. It it far better to apply split-thickness Thiersch or Wolfe grafts after granulations have formed. (6) The *general condition of the patient* affects repair—starvation, dehy-

Treatment of Wounds Produced by Mechanical Force.—*Arrest hemorrhage first.* This may be done by a tourniquet or by a tight bandage. If it is an extensive wound, the patient should be removed to a hospital. The wound is covered with sterile gauze and bandaged tightly. If an elastic bandage is available, it is applied. Many wounds which are relatively clean are contaminated by the first-aid attendant. Such contamination may be due to unclean hands, bacteria from nose and throat, washing the wound and surrounding tissue in such a manner that dirty water enters the wound, strong antiseptics, and rough handling. First-aid workers should be taught to cover the wound with a large amount of sterile gauze, bandage the part, and apply a temporary splint.

Then treat the patient as a whole for shock. This has been discussed in Chapter 14. However, a diagnosis as to the extent of the injury, the *patient's general condition, and the presence of multiple injuries must* now be made. Our experience in civil life has been the triple combination *of head injury, abdominal or thoracic internal injury, and superficial skin* wounds. In industry the hands are injured most. Lastly, one must be on guard for an injury in an individual who has had diabetes, a stroke, etc. When reaction has occurred, the wound should be treated. Let us assume that it is a lacerated and contused wound, filled with grease and dirt. The indications are clear and may be categorically stated as follows: (1) Control the hemorrhage by placing clamps on bleeders or leaving the tourniquet in place; (2) scrub thoroughly; this removes contamination and enables the surgeon to (3) make a careful inspection; (4) surgically remove any dead or devitalized tissue (débridement); (5) ligate the vessels and repair the nerve, muscles, tendons, and skin.

By *repair* we mean the restoration of continuity. This does not always mean functional restoration but may be only anatomic. Nor does it imply that repair will be made by like tissue. In general, the more highly specialized a tissue, the less its ability to regenerate itself. Of the five primary tissues, nervous tissue is perhaps most highly developed. Therefore, although the neurilemma of a nerve *fiber* may heal and the axis cylinder may grow down its sheath of Schwann if myelin is present, the cell *body*, if destroyed, will not regenerate itself. We have all the nerve cells we are going to acquire at birth; these may develop but will not increase in number nor regenerate when destroyed. Muscle tissue is also highly specialized and when it is destroyed repair takes place not by muscle but by connective tissue. Therefore, in sewing muscle, small amounts are included in the loosely tied sutures. Vascular tissue is partially able to regenerate. Epithelial tissue likewise is not entirely able to regenerate, for after the skin has healed there is an absence of sebaceous glands, sweat glands, and hair follicles in the scar. Connective tissue, the least specialized, is completely able to regenerate itself. (This includes tendon, bone, and cartilage.)

7. Tetanus antitoxin (5,000 units), or toxoid if the patient has been previously immunized, is given subcutaneously, and if the wound is badly contaminated, gas bacillus antitoxin is given in combination with it.

8. Besredka has claimed that anaphylaxis does not occur in patients under general anesthesia. However, in those with previous serum treatment or allergy, tetanus antitoxin is best administered in broken doses. The new tetanus vaccine now being used will greatly simplify the problem for the patient.

Accidental wounds are not often primarily contaminated; they may become infected when they have gone untreated for more than eight hours. In the stage of contamination, bacteria are lying on the wound surfaces and can be removed therefrom by mechanical means. In the stage of infection, bacteria have multiplied and penetrated the tissues so that their mechanical removal is no longer possible. It is obvious that the most favorable time for treating accidental wounds is in the period of contamination or six days later when local immunity is high and the process of getting bacteria out of the tissue hideouts will not be accompanied by their dissemination.

Reid quotes Billroth as follows:

> If you inject a drachm of putrid fluid into the subcutaneous cellular tissues of a dog, the result will be inflammation, fever, and septicemia. If you make a large granulating surface on a dog, and dress it daily with charpie soaked in putrid fluid, it will have no decided effect. On the borders of the new inflammatory formation the lymphatic vessels are closed; on the granulating surface there are no open lymphatic vessels, hence no reabsorption takes place.

The *treatment of contaminated wounds* should consist in the removal of as many bacteria as possible without inflicting any injury upon the tissues which can impair their power of resistance. No antiseptic has ever been devised which is not on the whole more injurious to leucocytes and tissue cells than to the bacteria. Antiseptics quickly lose their bactericidal power when mixed with body fluids. In fact, they make serum and blood a first-class culture medium. Tincture of iodine is perhaps the most dangerous antiseptic which can be applied to a wound. In contact with body juices it has a slight bactericidal action, and it injures the tissues with formation of scab under which bacterial growth can flourish with disastrous results. Fingers and hands are lost because of treatment of trivial cuts with iodine. If the cut finger be placed under running isotonic saline, the wound held open and thoroughly washed out, hemorrhage encouraged, and covered with a sterile, dry dressing, the wound will nearly always heal by first intention. Dakin's fluid is still used in infected wounds and burns. It is a poor antiseptic but it does increase exudation; however, at the expense of cell injury. Surface irrigation with physiological saline washes off transient contaminators and the subcutaneous injection (at a short distance) of the solution will infiltrate under the wound and cause it to weep copiously without cell destruction

dration, hemorrhage (due to low plasma or inadequate protein content), alkalosis, acidosis, or avitaminosis (as in scurvy and pellagra) interferes with wound healing.

If the injury is in an extremity, as is usually the case, the tourniquet may be left in place. This provides a bloodless field and enables the physician to clean and inspect the wound thoroughly. In any wound in which there is the slightest doubt concerning the depth or the injury to associated structures, general anesthesia should be used. If the wound is thoroughly cleaned within six to eight hours, infection is unlikely.

A method of sterilization which we have used with good results may be outlined as follows:

1. Aseptic surgical technique is employed (face mask, hands, and arms scrubbed for ten minutes; sterile gown) as for any major operation.

2. Gross cleaning. The skin about the wound is shaved and then is scrubbed thoroughly with soap and water and a soft brush. If grease or dirt is present, some cleaning agent is used. This should be a fat solvent (such as ether or carbon tetrachloride) or Boraxo, Sapolio, or other cleaner. Of course, such agents are irritating and should be thoroughly removed with sterile physiological salt solution. All visible foreign material is picked out.

3. Sterile towels are now placed widely about the area, and this is followed by irrigation of the wound with 1 or 2 liters of sterile isotonic salt solution. The surgeon puts on sterile gown and gloves.

4. All dead tissue is trimmed away and the flushing is repeated. Any filaments of tissue floating in the irrigating fluid are removed.

5. The tourniquet is released and all vessels are now carefully tied with chromic catgut, No. 00 or No. 000.

6. After change of gloves by the surgeon, tendons and nerves are repaired (see Chapter 3) and the wound is closed loosely by interrupted silk sutures. These should be simple (through-and-through) stitches and should be tied so loosely that there remains a gap of about one-fourth inch between the skin edges. If the wound is a deep and badly macerated one, or if it has been "washed out" by the untrained at home or if strong germicides have been used or if it is not treated until after eight hours, it should not be sutured. If the wound is first seen after twelve hours, infection is presumed to be present: no sutures are used, and the wound is left wide open until the danger of infection is over, five to six days, and then closed. In the latter instance, silk must not be buried in the tissues for it will act as a foreign body should infection develop. In the presence of an active infection it is best not to attempt the repair of tendons or nerves because suture lines may slough but to be content to secure drainage and remove loose foreign bodies. Rubber drains or gauze wicks are not used for they are foreign bodies. Wounds are either left open or closed loosely.

immunity is established the fracture is properly reduced and maintained. (See Chapter 21.) Joint cavities will heal if not traumatized. They should be irrigated with isotonic saline and closed. To leave them open results in infection and ankylosis—this is true even if the wound is old and if the primary wound is left open. Obviously if infection is already present the joint cannot be closed.

Nerve and tendon injuries sometimes are difficult to distinguish from each other. Cases have been reported of the inadvertent suture of one to the other. This may be avoided if a few rules are observed. The motor and sensory changes due to median, ulnar, and radial nerve injury in the upper extremity and of tibial and peroneal in the lower extremity are not hard to remember and offer characteristic signs (see Chapter 18). Tendon injuries are easily diagnosed by asking the patient to flex or extend the suspected tendon. At operation tendons retract and nerves do not. *If both are injured, the latter should be repaired first since they* usually lie deeper and there should be a minimum of handling of severed nerves after they have been repaired. Koch emphasizes the following principles: (1) gentle handling; (2) minimum of suture material—use fine silk; (3) protect line of suture with areolar or fatty tissue; (4) if the repaired tendon has a wide destruction of its sheath or if it is pulled away from its sheath, surrounding smooth parts of the sheath are brought over or fascia or tendon is secured from other parts of the body; (5) rest in splints in a position without tension for three to four weeks. (See Chapter 21.) Nerves are sutured with a minimum of fine silk. Knots are on the outside. Suture lines are covered by areolar tissue or fat or fascia so that adhesions do not form, and relaxation of paralyzed muscles is obtained by proper splints until reinnervation occurs. If a piece of nerve has been avulsed, end-to-end suture may be accomplished by freeing the nerve from areolar tissue of neighboring blood vessels above and below the site of injury, bringing the limb into flexion, transferring the nerve into a new position, as, for example, the ulnar from behind the medial condyle to the volar surface of the elbow. Nerve grafts may be tried and have been successful in extensive loss of substance.

After the deep structures have been repaired, the skin must be closed or covered with grafts. Koch lists the following rules for free grafts of intermediate thickness, free grafts of whole thickness, and pedunculated flaps when applied to the extremities:

(1) Use the simplest procedure that will give the desired results; (2) primary healing is desirable in a large wound which is always subject to infection; therefore a graft may be used which may not be ideal from the standpoint of appearance and function to get covering; later this may be replaced; (3) if the raw surface has a normal blood supply and if structures which require a covering of subcutaneous tissue are not exposed (tendons, nerves, large blood vessels, bones and joints), a free graft of intermediate thickness is best; (4) if the above structures are widely exposed so that they cannot be covered with skin and subcutaneous tissue from either side, a pedunculated flap from adjacent or distant tissue must be secured, because free grafts of skin and subcutaneous tissue are not apt to

or injury. If, in addition, sulfadiazine is given by mouth in the dose of 0.3 to 0.5 Gm. per pound of body weight as a prophylactic measure, infections will be rare. If the patient cannot take the drug by mouth, it may be given intravenously. Penicillin, 30,000 to 40,000 units intramuscularly every three hours, is added in badly contaminated wounds. Although many surgeons advocated the use of sulfonamides locally, our policy has been to avoid them because of their local irritating action (see Chapter 5). Penicillin has been used in low concentration (500 to 1,000 units per cubic centimeter) and is effective. In strong concentration it may be toxic for lymphocytes and leucocytes. Many antibacterial substances have failed as local chemotherapeutic agents because the complete pattern of requirements has not been met—that is, they are toxic, or they do not act in the presence of blood and pus or other environmental changes (iodine and mercury destroy surface bacteria and cells and create a favorable environment for bacteria to grow). Sulfonamides are slow, and they are inhibited by para-aminobenzoic acid and the presence of sloughs; they are toxic and act as irritants. Dry calcium penicillin is irritating but not so much as the sodium salt which is irritating in concentrations of 200 to 500 units per cubic centimeter. Penicillin is destroyed in the presence of gram-negative bacteria. Recently streptomycin has been used because it is effective against many gram-negative bacilli and some gram-positive organisms.

Having cleaned the wound, given antitoxins, and started chemotherapy, we turn our attention to the structures which have been injured and proceed with the repair.

In the *hands* one looks for injuries to blood vessels, bones, nerves, tendons, and joints.

When larger *blood vessels* are injured or torn, there is increasing swelling, discoloration, absence of pulse, coldness, and adventitious sounds in combined arterial and venous injury with venous engorgement. In this connection a word should be said about the removal of a foreign body which is buried or protrudes from the skin. In place there may be little sign of bleeding. When removed, an exsanguinating hemorrhage may occur due to the fact that the steel or wood piece has acted as a plug. All foreign bodies should be removed under general anesthesia with tourniquets on extremities and through a liberal incision to control bleeding by temporary occlusion of the principal artery or vein.

Injuries to *bones* and *joints* are not difficult to diagnose. Emergency treatment consists of the application of sterile dressings and splints, especially in compound fractures. In the hospital under aseptic conditions the wounds are cleaned, the fracture reduced, and the wound loosely closed if seen within eight hours. If not, the wound is left open, the fracture is reduced, and reduction is maintained by plaster cast. Six days later the wound may be closed. In very late and badly contaminated or infected cases, immobilization is secured by traction; then when local

Hidrosadenitis Suppurativa.—Hidrosadenitis suppurativa (acne conglobata, perianal pyoderma, axillary pyoderma, hydradenitis suppurativa, pyogenic granuloma, pyodermia, recurrent axillary or perianal furunculosis) *probably includes a number of closely related chronic inflammatory diseases of the skin.* The types which occur in the axillae, around the nipples, and in the inguinal, genital, and perianal regions are probably due to a chronic infection of the apocrine glands in these regions (see Chapter 22). These are specialized sweat glands located in the regions mentioned, giving off a characteristic odor. They may be involved in Paget's disease of the nipple and vulva. It is true that in most of the patients there is an associated diffuse acne vulgaris, multiple comedones, and sebaceous cysts. All of our patients have been men. The lesions may be limited to the axillae (axillary hidrosadenitis), the areolae of the breast (mammary hydrosadenitis), or the genital region. *Undoubtedly there is a constitutional predisposition to the disease.*

The lesions are notoriously chronic and are characterized by the formation of papules, pustules, large abscesses, chronic indurated sinuses, and a general fibrosis of the area. Patients are harassed by one abscess after another and by a continual drainage of pus. There is extensive undermining and burrowing involving wide areas which become progressively worse. The lesions resemble tuberculosis or fungus infections of the skin.

All sorts of remedies have been tried; namely, vaccines, x-ray treatment, local ointments and antiseptics, stilbestrol, sulfur baths, liver extract, Fowler's solution, low fat diet, and thyroxine therapy.

Excision of the apocrine gland-bearing areas and surrounding skin gives the best and quickest results. The fibrous and inflammatory tissue in the fat and connective tissue should also be removed. Then the entire area may be covered by skin flap shifts or split-thickness grafts.

Other bacterial diseases of the skin are as follows:

Infectious eczematoid dermatitis results from slight injuries, or scratches and is due to the staphylococcus as a rule. Often it is associated with ingrown toenails, furunculosis, and paronychia. It responds well to penicillin.

Impetigo contagiosa and other impetiginous infections are probably due to staphylococcus and streptococcus infection. The familiar blister and crust and spread of the disease is a common observation in any skin clinic. The treatment with penicillin ointment yields good results. Other forms of therapy include gentian violet solution, 1 per cent locally, silver nitrate, 10 per cent, and ammoniated mercury; adhesive tape over the lesions often results in early healing.

Systemic Integument Diseases

Many skin lesions are merely outward manifestations of systemic disease. These are considered elsewhere in the book. The *purpuras* are

take, and they would probably not give satisfactory functional results if they did; (5) whole-thickness grafts may be used in freshly made, clean, raw surfaces where a covering is needed that will not contract much, and will be thick enough for protection. Uniform pressure over injured tissues checks persistent oozing of blood and serum and it provides a substitute for the normal outer covering of skin and fascia.

Immediate skin grafts of all types should be used on extensive wounds seen within six hours which are too large to be covered by sliding flaps. Abrasive wounds may be covered after careful cleansing with split-thickness graft; finger tips, with full-thickness grafts. Wounds leaving exposed tendons need skin and subcutaneous tissue. This is often accomplished by a pocket flap from the anterior abdominal wall or thigh for the hand and a pedicle or pocket flap for the ankle, foot, or knee made from the other leg. Abdominal flaps created in the regions of the superficial epigastric artery and vein may be transferred by leaving only the inferior margin attached instead of attachment at both ends. This is possible because, as in scalp flaps, the blood supply comes from below and the flap gets ample nourishment through its inferior attachment. Full-thickness grafts taken from the neck and clavicular and postauricular and forehead regions have been found to give good results in the repair of facial defects; that is, eyelids, nose, and about the mouth. Although these donor sites afford little skin, it is usually enough for the defects mentioned. For the nostril border and tip and columella, two skin surfaces and cartilage between them are needed. The ear border is an accessible donor site which may be easily repaired after the graft has been taken.

Skin color is due to pigment and to the amount of blood flow. If it is necessary to take skin which does not match, pigment may be introduced for cosmetic reasons.

A good rule to follow is: use available tissue without graft if possible. This may often be accomplished by tissue shifting and rotation as in Z plastics or multiple Z plastics which are especially useful in freeing contractures or in the repair of excised scars (see diagrams in Chapter 3).

Wounds are not molested for at least eight days unless there is severe pain, bleeding, excessive exudation, progressive swelling, or severe systemic reaction. The part is immobilized and the patient should be put to bed if the wound is extensive. In less extensive wounds thorough scrubbing, careful removal of foreign bodies, and the control of hemorrhage are also important considerations. Sutures should be used sparingly if at all and introduced loosely. Rest to the part is imperative.

Skin Infections

Many of the ordinary skin infections have been considered in Chapters 5 to 9. More are beyond the scope of this book. There remain a few which are of interest to the surgeon which should be described here.

fibromatosis and tuberous sclerosis discussed below are also systemic afflictions. *Metastatic skin lesions and lymphoblastomas are often first* noted by nodules in the former and by mycosis fungoides in the latter.

Diseases due to fungi are discussed in Chapter 7. The surgeon is occasionally called upon to remove a toenail infected with tinea *(Trichophyton gypseum* and *purpureum);* the nail bed is then treated with x-ray. Protozoan diseases of the skin, of which syphilis is the most important, are discussed in Chapter 9.

Throughout the text reference is made to skin manifestations. This discussion is intended to show the interrelation of systemic disease with skin manifestations and the reverse.

New Growths in the Integument

Epidermoid Carcinoma of the Skin.—There are two main varieties of epidermoid carcinoma: (1) adult hornifying squamous carcinoma—acanthoma, *prickle-cell cancer, or spinocellular carcinoma and* (2) *basal-*cell carcinoma or rodent ulcer. Occasionally both varieties are present in a single lesion. A third variety is described by Ewing: transitional-cell carcinoma (lymphoepithelioma). It is seen over the tonsils, in the vault of the pharynx, in the nasal passages, at the base of the tongue, and in the nasopharyngeal tissues. It is infiltrating and involves lymph nodes early. The undifferentiated cells in this type of growth make it radiosensitive.

Squamous-Cell Carcinoma.—Squamous-cell carcinoma is often called rose cancer because of its elevated edges; it is seen on exposed parts such as the nose, lips, cheeks, eyelids, ears, and hands, and occasionally in old burned areas (Marjolin's ulcer). It is also encountered in the mouth, tongue, anus, and cervix and in these locations is more malignant. This growth is apt to occur at junctures of stratified squamous epithelium and the moist epithelium of mucous membranes.

When it occurs on the surface the growth is usually an ulcerative one with raised edges, while in the mouth it may be elevated as well. In general, the elevated variety is less malignant. In histological sections the cells may be seen breaking through the basement membrane into the subcutaneous tissues. Various stages of *epithelial cells are seen, some in* concentric whorls. The individual cells show intercellular bridges or spines, also keratinized areas (epithelial pearls). Forerunners of squamous-cell carcinoma have been listed by Eller and Anderson. Some of the more common are syphilis, leucoplakia, radiodermatitis, moles, senile keratosis, seborrheic *keratosis, kraurosis vulvae, occupational* keratodermias (tar, pitch, arsenic dust, oil, heat), lupus vulgaris and tuberculous cutis, lupus erythematosus, chronic ulcers (varicose, pellagrous, fistulous), Paget's disease of the nipple, cicatrices, cutaneous horns, Bowen's disease, extramammary Paget's disease, papilloma of the tongue, xeroderma *pigmentosum, blastomycosis, inflammatory* dermatoses

often associated with splenomegaly (Chapter 22). Xanthoma, cholesterosis, and other lipoid disturbances will be found in this chapter under Adipose Tissue. *Pellagra* is due to vitamin B deficiency, as is also cheilosis. *Scleroderma* is discussed with Raynaud's disease (Chapter 6). A more comprehensive view of diffuse scleroderma and also of *disseminated lupus erythematosis* is that of its involvement of collagenous tissues. The cause of scleroderma and of lupus is unknown. They may involve the connective tissue of such unrelated organs as the skin, esophagus, spleen, kidney, pericardium, and retroperitoneal and periarticular tissues; therefore they may be representative of a system disease—namely, collagenous tissue.

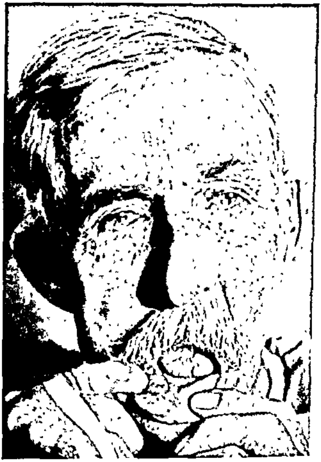

Fig. 135.—Early squamous-cell carcinoma of the lower lip in a man aged 70 years. There was lymphatic involvement. Complete excision resulted in a cure. (See Fig. 115.)

Another possibility is that they are primarily due to obliterative changes *in the smaller arterioles*. *Scleredema* is characterized by nonpitting edema of face, neck, scalp, conjunctivas, and thorax, rarely the extremities, and associated pleural, pericardial, and synovial effusions. Complete recovery usually occurs, and in this way, as well as in the changes in the lungs, esophagus, heart, and decalcifications of bones, it differs from scleroderma. *Dermatomyositis* is mentioned in Chapter 21 and it, too, may be a "system disease" of connective tissues. New growths such as neuro-

Fig. 136.—Diagram showing block dissection of the neck in carcinoma of the lower lip with metastasis. This is a logical operation because carcinoma of the lower lip rarely metastasizes below the clavicle. The dissection includes the removal of the submaxillary nodes, the submaxillary and a portion of the parotid gland, the lymph nodes of the jugular chain with ligation, and removal of the internal jugular vein. Carcinoma of the lip near the angle may metastasize to one side of the neck. This may also be true in metastatic carcinoma of the floor and roof of the mouth, tongue, buccal mucous membrane, cheek, and mandible. The nodes of the opposite side may be sampled for biopsy.

If both sides of the neck are involved, dissections are carried out on each side toward the midline and all structures removed en masse. The internal jugulars are not removed. The transverse incision is carried from one angle of the jaw to the other.

A. Insert shows incision for unilateral neck dissection. Skin flaps are made. The sternomastoid is divided near its sternal and clavicular attachment. The internal jugular is divided between double ligatures and the carotid sheath is dissected away. Fat and nodes are removed over the scaleni and trapezius. The posterior belly of the digastric and stylohyoid muscles is divided from the hyoid attachment. The submaxillary gland and its duct are freed after dividing the external maxillary artery and vein. The jugular bulb is found in front of the styloid process and is divided between double ligatures and removed. Then the upper end of the sternomastoid and digastric are divided near their mastoid attachment. The lower end of the parotid is removed.

B. Structures remaining after complete dissection. *The stylohyoid is erroneously shown to be intact.*

the proximity of skin lymphatics. In the latter there is early involvement of the superficial lymphatics, thereby inducing a perilymphatic fibrosis; in the former the malignant cells are widely disseminated first and then the lymphatics are involved. The early surgeons called it *noli-me-tangere* (do not touch me) because of this fact. When diagnosed early it may be excised, but if seen late it should be treated by x-ray and radium for the best results.

Carcinoma (squamous or basal) in the mouth is best treated by radium, although if seen early, excision of the growth with a wide margin and dissection of anatomic glands may be done.

Fig. 138.—Late squamous-cell carcinoma of the lower lip in a man aged 40 years. Note involvement of submental and submaxillary glands. (See also Fig. 115.)

Squamous-cell carcinoma may arise on a basal cell. Therefore, a biopsy must be inclusive so that local excision may be accompanied by gland dissection if necessary. A second type of basal-cell carcinoma is really related to the dermal glands which it tends to reproduce. This is known as *adenoid epithelioma* of the skin. There are two main subdivisions of this group: (1) adenoid cystic epithelioma (Brooke)—multiple nodules of the face, neck, and chest in children at the age of puberty and (2) *simple adenoid epithelioma* seen in or near rodent ulcers. The former should be individually removed by excision or cautery when

(psoriasis, lichen planus, eczema). Clinically, it is first seen as a small scab or scale. This is picked off, leaving a small raw surface; then another scab forms, etc. Finally the ulcer remains and grows in size. In the lip it is frequently a small fissure and is usually on the lower lip. If untreated, it grows extensively, destroying even bone and cartilage. Metastasis occurs to the regional glands by embolism, not by permeation. It is *rarely seen below the clavicles although distant metastases have* been reported. It is important to remember that the metastatic area in the submental region may be the first evidence of a carcinoma of the floor of the mouth. Biopsies should be done only after a careful search has been made for the primary site of the cancer. Treatment consists in complete excision of the growth together with the affected glands. This implies a wide neck dissection. If on the face, in the mouth, or in the cervix, radium and x-ray are preferable to excision, but complete surgical removal of nodes and submaxillary gland should be done.

Fig. 137.—Basal-cell carcinoma of the face. (See Fig. 120.)

Carcinoma Basocellulare (Basal-Cell Carcinoma).—Carcinoma basocellulare (basal-cell carcinoma) occurs usually on exposed surfaces. The cells come from the stratum germinativum, are regular in size and shape, have no intercellular spines, and do not progress to the squamous or cornified stages of maturity. The growth begins as a smooth elevation and burrows down into the skin and laterally, elevating the edges. It may *destroy* bone and cartilage. It does not metastasize but will recur locally unless completely removed or destroyed. The reason for early metastasis in squamous-cell and none in basal-cell is thought to be due to

Melanoma Malignum.—Melanoma malignum (melanosarcoma or melanocarcinoma) is a very malignant growth of the skin (also of the eye and subungual region). It develops from the pigmented mole (an *atavistic remnant of hair feelers in lower animals*). *The chromatophore* or pigment cells of the skin are supposed by some to be of connective tissue origin and by others to be of epithelial origin. The growth may be started by a single trauma or by multiple or continued irritation. It grows very rapidly and metastasizes by the way of the blood stream and lymphatics, the glands becoming pigmented also. Death results from metastasis to the liver, brain, and lungs. The only treatment is prevention. A mole which is continually being traumatized should be excised with a small margin of normal tissue. X-ray is used without avail in the disseminated case.

Carcinoma of Branchial Cleft Rest.—Carcinoma of a branchial cleft rest is a rare type and is often confused with the more common lymphoblastomas described in Chapter 17. The tumor should be excised completely.

Benign Tumors and Cysts of the Skin.—

Hemangiomas and Lymphangiomas.—Hemangiomas and lymphangiomas are described in Chapter 17. Sometimes there is a combined hemangiolymphangioma. Myomas (dartoic and leiomyoma) are rare; also rare are chondromas which may be in the skin as rests and osteomas which may be confused with calcifications of inflammations and cysts. Some of the more common benign skin tumors and cysts are briefly described in the following paragraphs.

Wen or Sebaceous Cyst.—A wen or sebaceous cyst is an extremely common lesion. It is due to a plugging of the sebaceous gland duct, which fills with oily sebum, forming a cyst containing malodorous cheesy matter. The skin is usually adherent to the cyst but, as a rule, can be easily dissected loose. Sometimes it becomes infected and presents the picture of an acute abscess. In this case it must be drained. However, the only cure is the excision of the cyst wall. Cholesteatomas are closely related and are due to scaling and desquamation of epithelium. They are lined with stratified squamous epithelium and filled with sebaceous material and cholesterol crystals. They are seen in chronic mastoiditis and in the renal pelvis, brain, and hypophysis.

Dermoid Cysts.—Dermoid cysts occur in the skin and contain epidermis, derma, and dermal glands and structures (sebaceous material, hair, and even nails). They are probably best explained by Cohnheim's hypothesis. When they occur congenitally they are called *true dermoids* to distinguish them from *implantation dermoids* which result from traumatic displacement of epithelial fragments. True dermoids occur on the scalp, neck, back, median line of chest and abdomen, sacral region, and buttocks.

they show signs of growths because they are usually benign. The latter requires complete excision.

Bowen's Disease or Precancerous Dermatosis.—Bowen's disease or precancerous dermatosis is a chronic lesion of the epidermis which represents a specific form of precancerous keratosis. The lesions are multiple and pink or red and are covered with a thickened horny layer. The cells are irregular and anaplastic but hold to the base line and therefore the lesion has been called *intraepidermic carcinoma. Even after the rete* pegs have been traversed and carcinoma cells appear in the underlying tissue, they do not, as a rule, metastasize. Thus many squamous-cell carcinomas may be present over the body at the same time. This failure to metastasize has been attributed to the great fibrosis and lymphocytic infiltration about the lesions. The *treatment* is excision with related gland if they are involved—this is rare. Since so many areas must be removed, operations are done in stages so that too much denudation and plastic repair or skin grafting is not done at any one time. (See Figs. 116-119.)

Sarcoma of Skin.—Sarcoma of the skin may be primary, and take origin in the subcutaneous tissue and fascia (reticular sarcoma), or secondary. Fibrosarcoma, fibroma (not including keloids), lipomas, hemangiomas, lymphangiomas, angioendotheliomas, neurofibromas, neurolemmomas, lymphosarcoma, malignant melanoma, and metastatic carcinoma may occur in the subcutaneous tissue. Variations from benign fibroma to cellular fibrosarcoma occur and are easy to differentiate in extreme but not borderline cases. *Multiple hemorrhagic sarcoma (idiopathic multiple pigmented sarcoma of Kaposi)* is a special type starting with multiple lesions in the legs. These lesions start as bean-sized, reddish nodules with telangiectasis; soon the legs are greatly enlarged. Visceral involvement may cause hemorrhage, diarrhea, fever, and cachexia. The internal new growths are not metastases but are probably primary.

The histological picture is that of angioma with young connective tissue cells merging into definite sarcoma.

X-ray is the treatment of choice but is apt to be unavailing.

Lymphoblastic Disease.—Lymphoblastic disease is often accompanied by skin manifestations as exemplified in leucemia cutis, lymphatic leucemia, and myelogenous leucemia with skin lesions. Discrete lesions are those of lymphoma, lymphocytoma, Hodgkin's disease, and *mycosis fungoides* (granuloma fungoides). X-ray may give temporary relief.

Endothelioma.—Endothelioma of the skin is very rare. *Metastatic* lesions are not uncommon in late carcinoma. If the primary source is known, a nodule in the skin may settle the chance of operative cure. If the primary source is not known, it is well to withhold biopsy until an exhaustive search has been made; this is especially true in lesions about the mouth.

Melanoma Malignum.—Melanoma malignum (melanosarcoma or melanocarcinoma) is a very malignant growth of the skin (also of the eye and subungual region). It develops from the pigmented mole (an atavistic remnant of hair feelers in lower animals). The chromatophore or pigment cells of the skin are supposed by some to be of connective tissue origin and by others to be of epithelial origin. The growth may be started by a single trauma or by multiple or continued irritation. It grows very rapidly and metastasizes by the way of the blood stream and lymphatics, the glands becoming pigmented also. Death results from metastasis to the liver, brain, and lungs. The only treatment is prevention. A mole which is continually being traumatized should be excised with a small margin of normal tissue. X-ray is used without avail in the disseminated case.

Carcinoma of Branchial Cleft Rest.—Carcinoma of a branchial cleft rest is a rare type and is often confused with the more common lymphoblastomas described in Chapter 17. The tumor should be excised completely.

Benign Tumors and Cysts of the Skin.—

Hemangiomas and Lymphangiomas.—Hemangiomas and lymphangiomas are described in Chapter 17. Sometimes there is a combined hemangiolymphangioma. Myomas (dartoic and leiomyoma) are rare; also rare are chondromas which may be in the skin as rests and osteomas which may be confused with calcifications of inflammations and cysts. Some of the more common benign skin tumors and cysts are briefly described in the following paragraphs.

Wen or Sebaceous Cyst.—A wen or sebaceous cyst is an extremely common lesion. It is due to a plugging of the sebaceous gland duct, which fills with oily sebum, forming a cyst containing malodorous cheesy matter. The skin is usually adherent to the cyst but, as a rule, can be easily dissected loose. Sometimes it becomes infected and presents the picture of an acute abscess. In this case it must be drained. However, the only cure is the excision of the cyst wall. Cholesteatomas are closely related and are due to scaling and desquamation of epithelium. They are lined with stratified squamous epithelium and filled with sebaceous material and cholesterol crystals. They are seen in chronic mastoiditis and in the renal pelvis, brain, and hypophysis.

Dermoid Cysts.—Dermoid cysts occur in the skin and contain epidermis, derma, and dermal glands and structures (sebaceous material, hair, and even nails). They are probably best explained by Cohnheim's hypothesis. When they occur congenitally they are called *true dermoids* to distinguish them from *implantation dermoids* which result from traumatic displacement of epithelial fragments. True dermoids occur on the scalp, neck, back, median line of chest and abdomen, sacral region, and buttocks.

Epidermoid Cysts.—Epidermoid cysts are congenital or traumatic, are usually filled with thin fluid, and are lined by a simple epidermal lining. They differ from dermoids in that there are no definite dermal structures. They may arise spontaneously or they may occur as a result of transplantation of epidermis by accidental injury or by downgrowth from a curetted ulcer. Rarely they are found on the palms or soles as a result of injury.

Branchial Cleft Cysts, Thyroglossal Duct Cysts, and Pilonidal Sinus.—These all represent developmental malformations. They are lined with epithelium and should be completely excised, including their cyst wall.

Wart.—A wart may be a true papilloma, or if there are multiple warts occurring in crops, they may be due to a filtrable virus. So-called "seed warts" are probably the former. For this type, excision or removal by cautery is best. The contagious types are often "aborted" by injecting

Fig. 139.—Pigmented nevus (mole). Benign. (See also Fig. 112.)

iodine or using x-ray. Soft warts may be simple folds of skin from unknown causes. A peculiar cauliflower type known as *condyloma latum* (venereal wart) may be due to gonorrhea or syphilis. It may be removed by the cautery or by nitric acid. Many of the venereal types disappear after the cure of the causative disease. Condyloma accuminata is due to any irritation which is prolonged. It represents a defensive reaction or degeneration of the skin. Podophyllin has been employed in their treatment; removal may be easier and quicker if only a few condylomas are present.

Mole or Pigmented Nevus.—A mole, or pigmented nevus, is a congenital malformation usually occurring in brunettes. Studies have been made of the nature and origin of two abnormal formations of the human skin, the lentigines and vascular moles. The lentigines of human beings are remains of tactile organs, which in earlier developmental stages had

the form of strongly pigmented warts, with tactile hairs; vascular nevi are enlarged sinuses that are the remainders of former tactile hairs. The histological examination of the nevus acanthosiformis suggests an atavistic formation dating back to the period of phylogenic development when the skin served as a respiratory organ; that is, to the amphibious stage. The mucus-secreting glands in cutaneous neoplasms are a proof of the amphibious ancestry of human beings. In members of the white race there occur nevi with and without hairs, while hairy nevi do not occur in Negroes. The skin of the white race developed from the skin of the amphibians by way of the land-inhabiting species with hairy skin.

Fig. 140—Plexiform neurofibroma of the face.

Negroes are free from hairy nevi because in the phylogenesis only one type of skin, that of the amphibians, is present. (Samberger.) Moles vary in size, shape, and color and may be flat or elevated. They should be excised if exposed to repeated trauma.

Fibromas.—Fibromas may occur as small hard nodules in the subcutaneous tissues. True fibromas are rare. The purest type is not regarded as a neoplasm but as an overgrowth of scar tissue *(keloid)*. A very cellular type, locally malignant, occurs in the flat muscles of the anterior abdominal wall, usually in young parous women *(desmoid, Zellreiches fibroma)*. It is an unencapsulated infiltrating fibroma of fascial

or aponeurotic origin with a *microscopic appearance which varies from* that of a fibroma to that of a cellular low-grade fibrosarcoma. The tumor should be radically excised, including muscle fascia and parietal peritoneum. Many desmoids are *radiosensitive and therefore x-ray therapy* may be used alone or postoperatively. We have seen two desmoids in men. Women should be warned against future pregnancies as the tumor is apt to recur following them. *Fibromas are commonly found in combinations,* as adenofibroma, fibromyoma, etc. In the skin they are usually associated with nerve sheaths—*neurofibroma* (in molluscum fibrosum and in Von Recklinghausen's disease). *These are slightly tender, hard nodules which* may occur anywhere on the surface of the body or in the brain (acoustic neuroma). Moreover, they are often associated with pigmented moles.

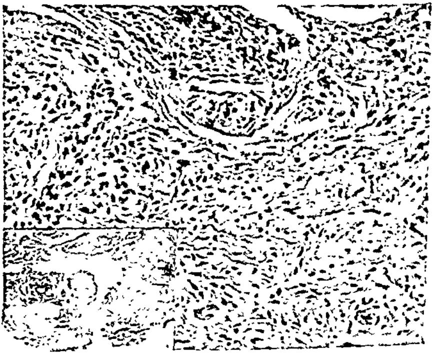

Fig. 141.—Neurofibroma of the face. Note the many nerves (left side of the low power) and the surrounding connective tissue. The high power shows nerves and fibromatous tissue.

Plexiform types *may* be very disfiguring. There is a definite familial tendency. A closely related tumor is the perineural fibroblastoma (Schwannoma or neurolemmoma) which grows from the *sheath of Schwann.* It *does not become malignant.* Treatment consists of excision of those growths which interfere with function.

Adenoma Sebaceum.—Adenoma sebaceum is seen in tuberous *sclerosis* (Epiloia) (tuberose sclerosis), a *syndrome* comprising epilepsy, mental deficiency, and adenoma sebaceum. There may be *congenital* enlargement of an extremity due to lymphatic obstruction; café-au-lait *spots* on the skin are common. Rarely there is splenic enlargement and in one of our cases a kidney tumor which proved *to be rhabdomyosarcoma* was pres-

ent. It is an ectodermal disease with cord changes and is related to neurofibromatosis. No satisfactory treatment is known.

Glomus Tumor.—A glomus tumor (glomangioma, angioneuromyoma) consists of a subcutaneous growth due to hyperplasia of the epitheliod or normal glomus cells. Normally there is an arteriovenous anastomosis in the skin of adults—not in infants. It is a coiled arteriovenous mechanism —Souquet-Hoyer canal. There is an afferent artery, then a coiled arterial organ, then a system of collecting veins; also preglomic arterioles with clear periglomic expansion zones furnished with neuroreticular mechanisms of sympathetic or myelinated nerves. Around the whole glomus is an outer lamellated collagenous zone. By this mechanism a large amount of blood can be quickly shunted into the skin to help regulate body temperature, local or general. The glomus mechanism is found chiefly on the digits, palms, and soles. Some are in the skin of the extremities and trunk.

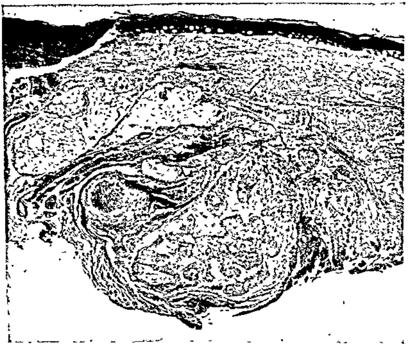

Fig 142.—Glomus tumor There are dilatation of the Souquet-Hoyer canal and hyperplasia of the cells surrounding the canal. These canals normally have smaller lumina but thicker walls than normal arteries, due to an increase in smooth muscle cells. The endothelial cells become cubold and the elastica fades out. Outside the muscle layer is the neuromuscular coat. The masses of cells in this tumor have been described as endothelioid, epithelioid, or a combination of nerve and muscle cells. The lesion is painful, due to pressure on nearby Pacinian corpuscles or on the nonmedullated nerve fibers within the tumor. Excision is curative.

Since none are found in infants, their body temperature cannot be regulated as easily. Clinically it is seen as a small growth which is extremely painful and is usually found on the extremities, often under the finger nails, and rarely, over the coccyx. The extreme sensitivity and pain are due to pressure on near-by pacinian corpuscles or the nonmedullated nerves it contains. The treatment is excision under local anesthesia.

ADIPOSE TISSUE

Eighteen per cent of the average person's weight is composed of adipose tissue. When fat is ingested, it is completely hydrolyzed during its stay in the intestine. The split into fatty acids and glycerine is the first step in absorption. Fat as such is rarely absorbed. Fatty acids are water soluble in the presence of bile. Fatty acids are transformed into phospholipids as an essential step in the resynthesis of fat. Insoluble fats are carried by the lymphatics to the blood—not to the liver. Cholesterol helps in this carriage and the blood plasma has neutral fat, phospholipids, and cholesterol esters. The liver takes an active part in fat transport. There is no doubt that some of this adipose tissue has a special function and is not merely connective tissue with fat cells.

Maximow doubted the origin of fat cells from fibroblasts and postulated their origin in part from undifferentiated mesenchymal cells about the blood vessels. Fat cells do not have the power to multiply—this is evidence of their high degree of specialization. (Wells.) There is ample evidence that some of it is glandlike in character. An illustration is the sucking-pad in the cheek. The primitive fat organ is closely related to small vessels and it originates from perivascular mesenchymal cells related to the reticulum. The fat organs, therefore, are formed from the same embryonic elements as the lymph nodes; that is, capillaries and reticulum cells of the vascular adventitia. This relationship is proved by the tendency for lymphoid tissue sometimes to replace fat tissue and conversely, as seen in the thymus. Also, the bone marrow is closely related to adipose tissue and this accounts for at least some extramedullary hemopoiesis. Adipose tissue may also be looked upon as a part of the reticulo-endothelial system. This is especially noticed in the omentum. When fat cells are distended with fat anywhere in the body, the organ in which this occurs need not necessarily be deficient in its function. This is also true of the individual fat cells. Very often the shrinkage of the organ necessitates a filling in of dead space, which the body will not tolerate, by fat. This is seen in atrophy of any organ in which there is a generous amount of fat deposit under the capsule of that organ. The importance of fat as a storage place for water is well known not only in the human being but also in the camel whose fatty hump is a water storage place and also in lower animals which hibernate. It is thought by some that essential vitamins such as vitamin C may be stored in this tissue. Therefore, it may be said that fatty tissue plays a role in water metabolism. Also, it has mechanical protective influence over important organs and tissues and it is also a factor in the regulation of body heat, for it is well known that the loss of heat through fatty tissue by convexion or radiation is less than over tissue not generously supplied with fat. Wells believes that adipose tisue may take on glandular function and may be intimately connected with glands of internal secretion. This is seen in cretins where glandular adipose tissue is found in the dorsocervical and interscapular regions until thyroid extract is administered. The perirenal fat in man exhibits some of the characteristics of glandular adipose tissue. The exact function of such tissue, of course, is not known. Adiposity in general may play an important role in the tendency toward disease and resistance (Chapter 10). Fat people are not, as a rule, good surgical risks.

Deposits of fat may vary in different parts of the body and have come to be known as: (1) general obesity due to dietary indiscretion; (2) that obesity which is general in distribution, particularly in the upper trunk, related to hypothyroidism; (3) that which is particularly noticed about the hips, related to pituitary disease; and (4) Steatopyga, bizarre strips of fat such as is seen in the Hottentot bushman type. General obesity may be an inherited characteristic or tendency. This is doubted by some who say the inheritance is environmental.

The various pathological deviations of fat aside from their distributions may be seen in lipomas, diffuse symmetric lipomatosis, as noted in Dercum's disease, adiposis dolorosa, and in Fröhlich's syndrome, dystrophia adiposa genitalis; also, in lipodystrophia progressiva in which the upper part of the body has lost fat, whereas the lower part below the waistline is generously supplied with fat. General obesity is another example of pathological deviations. Perhaps fatty tissue plays a part in general metabolism. This is exemplified by the interscapular fat organ's ability to convert carbohydrates into fat by way of glycogen deposits in fat cells. The presence of great deposits of fat in the cells need not interfere with normal metabolism of said cells since the cytoplasm is outside the fat and in close relation to the blood supply. There is no doubt that fat tissue is a part of the reticulo endothelial system and may play a role in immunity. When extensive fatty changes are produced in the liver and other parenchymatous organs by phosphorus and other steatogenic poisons, the fat, at least in part, comes from the adipose tissue depots, for extreme emaciation may interfere with the production of this fat metamorphosis. The disease of fatty tissue itself is seen in fat necrosis, both external and internal, the external type from the slight trauma as seen sometimes in the abdominal wall and the female breast and the internal type as seen following the presence of activated pancreatic juice in the abdominal cavity. Lipocaic, a hormone of the pancreas, is said to prevent fatty degeneration of the liver. Bile in the peritoneal cavity may produce necrosis, apparently through effecting tissue permeability so that enzymes escape from the pancreas. A disease known as sclerema neonatorum in which the adipose tissue becomes hard and rigid like chilled fat has been described. Sometimes this process is localized and the affected area may undergo necrosis even with subsequent calcification. This has been called adiponecrosis subcutanea neonatorum. The lipogranulomatoses are little understood and consist of a local necrosis of adipose tissue leading to tubercles formed by large numbers of lipophage cells and multinucleated foreign body giant cells. At times the fat is set free to form small oil cysts surrounded by a zone of macrophages and giant cells. These lipophage granulomas have been called tuberculids (Darier's and Bazin's induratum). They may become calcified. In addition, as has previously been mentioned, the role of fat in hypertrophy and atrophy of organs leads to replacement or disappearance when interference with the organ may occur. As an example of the former, the bone marrow fills in with yellow fatty marrow as opposed to the red marrow of early childhood, depending upon the need for blood cell formation. When bone is absorbed, its place is filled by fatty marrow. The heart and the pancreas may be so crowded by fatty tissue as to interfere with function. In chronic nephritis and pseudohypertrophic muscular atrophy, fat replaces the space left by shrinkage of the organ. It is suggested by Wassermann that in the fatty replacement of atrophic muscles the remaining capillary bed transforms itself with the intramuscular connective tissue into a new adipose tissue. In the common use of insulin for persons with diabetes there may be a localized melting away of the fat in the vicinity of the sites of injections. Nichols suggests that the concentration of insulin causes an active local combustion of carbohydrate which in turn causes active combustion of fat. Lastly, the diseases such as panniculitis or Weber Christian's disease, which is accompanied by attacks of fever or generalized lipoid necrosis of the subcutaneous tissue, is not explained as to cause. The process histologically resembles that seen in various forms of fat necrosis with inflammatory reaction such as is seen in traumatic fat necrosis. Gaucher's disease is also associated with disturbed lipoidosis and will be discussed in Chapter 22 under *Spleen*.

Specific Examples of Diseases of Adipose Tissue

Lipoma.—Lipoma is a tumor made of adult fat. It may occur anywhere in the body even where normally adipose tissue is not found (kidney, meninges, periosteum); however, it is usually found in the panniculus adiposus of the shoulders, back, and buttocks. We have

recently had a large retroperitoneal lipoma which protruded through the femoral canal. *Lipoma arborescens* is a multilobulated growth. Multiple lipomas are usually *neurolipomas*. Lipomas should be excised. This is usually easy if care is used to stay outside the capsule. Occasionally lipomas become malignant—liposarcoma—and reach an enormous size. There are two types, adult fat cell and embryonal lipomyxosarcoma. They should be widely excised. *Diffuse symmetrical lipomatosis* includes "fat neck" of Madelung, "adiposis dolorosa" of Dercum, dystrophia adiposa genitalis of Fröhlich. These may be related to pituitary gland dysfunction but this is not invariably so. In Dercum's disease there is often vasomotor instability, anhidrosis, hyperhidrosis which may be due to disturbances of sympathetic nervous system (see Chapter 18) and such trophic changes as loss of hair, pigmentation, and cutaneous ulcers.

Fig. 143.—Lipoma of neck.

Fat Necrosis.—Fat necrosis is usually focal. When pancreatic juice is released, as in acute hemorrhagic pancreatitis, the cleavage of fat by lipase is followed by soap formation and the deposit of small, white areas in the adipose tissue of the peritoneal cavity. It is the lipase rather than the trypsin which is responsible for the pancreatic fat necrosis. Pure pancreatic juice will not produce fat necrosis unless activated by intestinal juice or tissue kinases, and since the latter may be present at all times even bile introduced in the peritoneal cavity may affect tissue permeability so that pancreatic enzymes escape, causing fat necrosis.

Local fat necrosis is seen after trauma. In the breast this may resemble carcinoma clinically. A biopsy may be necessary to make the differential diagnosis.

Lipogranulomatosis.—Whenever fat is destroyed from whatever cause, proliferative reactions occur. Foreign body giant cells which are multinucleated appear as scavengers and there is tubercle formation with many lipophage cells. Sometimes there are oil droplets or cysts surrounded by macrophages and giant cells. Because of the nodular (tubercular) reaction these nodules have been termed *lipophage granulomas.* Bazin's erythema induratum and Boeck's and Darier-Roussy sarcoids are listed as tuberculids but may belong to lipogranulomas. These may become calcified. Erythema nodosum also causes skin nodules, especially in the lower extremities, and is related to rheumatic disease. It may be due to the streptococcus, to drugs, to syphilis, and to various other diseases. These lesions are transitory and should not be incised even though they may seem to be fluctuant.

Relapsing Febrile Nodular Nonsuppurative Panniculitis (Weber-Christian's Disease).—Relapsing febrile nodular nonsuppurative panniculitis is a disease of unknown etiology. The symptoms are recurring attacks of fever and subcutaneous inflammatory nodules over the body which regress, causing localized areas of atrophy. The microscopic picture is that of fat necrosis with inflammatory reaction. We have had one case which responded well to penicillin, 50,000 units, intramuscularly every three hours during the fever episode.

Xanthoma.—A xanthoma, or xanthelasma, is a tumor made of foamy cells which are yellow. These deposits, which contain cholesterol, are commonly seen under the eyes and are harmless but unsightly. They may be excised. More important is a disturbance of cholesterol metabolism which causes large deposits of cholesterol (in macrophage cells) in bones, tendons, and dura, with cholesterolemia. If associated with diabetes insipidus and exophthalmus, the condition is known as Christian's disease or Hand-Schüller-Christian's syndrome, a disease probably due to improperly metabolized lipoids and producing a cholesterin compound. Defects of the cranial bones are almost constant findings. Diagnosis is made by the following symptoms and signs: arrested development, complaint of pain on walking or a limp, diabetes insipidus, and exophthalmus. X-ray examination, bone biopsy, high blood cholesterol occasionally, and cutaneous xanthomas aid in establishing the diagnosis.

Gaucher's Disease.—Gaucher's disease (Chapter 22) is characterized by a disturbance of lipoid metabolism with anemia, splenomegaly, and hepatomegaly; the lipoid improperly metabolized is a *kerasin.*

Niemann-Pick's Disease.—Niemann-Pick's disease is a fatal disease seen in infancy, usually, though by no means invariably, in Jewish children. There is a brownish pigmentation of the skin, malnutrition,

retarded development, hepatomegaly, splenomegaly, decreased red cell fragility, leucocytosis, and generalized lipoid deposits. The lipoid improperly metabolized is a lecithin.

The Breast

Embryology

In early (8 mm.) embryos there is a thickening of ectoderm which extends ventrolaterally between the bases of the limb buds. This linear thickening is the milk line. In the future pectoral region of this line there is a downgrowth of the epidermis. From this downgrowth buds appear which elongate and form fifteen to twenty solid cords which become milk ducts. These branch in the mesenchymal tissue of the corium and will form later into alveoli. Externally they are covered by connective tissue. There is a lumen in the downgrowths except in the terminal swellings. Some of the cells which touch the connective tissue develop into basket cells of so-called myoepithelial nature. Where the milk ducts open there is a slight epithelial evagination which later becomes the nipple. In males the gland undergoes regression. In females the growth continues throughout childhood.

Anatomy

The breast is covered by skin, superficial fascia (panniculus adiposus), and strands of platysma (panniculus carnosus). The *superficial fascia* over the body is divided into (1) a fibroadipose layer (superficial) into which cutaneous nerves and vessels ramify and (2) a fibromembranous layer (deep) which is attached to the former. The deep layer in turn is loosely adherent to the deep fascia. In some areas of the body the superficial fascia is of great surgical importance. Colles' fascia in the perineum directs the course of urine extravasated from a ruptured posterior urethra, and the superficial fascia of the anterior surface of the thigh directs the course of a femoral hernia through the saphenous opening. In the mammary area the superficial fascia divides into an anterior layer, which covers the breast anteriorly, and a posterior layer, which lies under the breast so that the breast lies between the two. This is important because in abscess of the breast pus is prevented from involving the retromammary space and is directed anteriorly or around the periphery. These layers are closely approximated inferiorly and form a shelf which acts as a support for the breast. The posterior layer is attached to the deep pectoral fascia in the midline, and the latter is in turn attached to the periosteum of the sternum. Strands from the posterior layer permeate into the interlobular substance and are attached to the anterior layer—ligaments of Cooper. Lymph flow is directed along the ducts toward the nipple, peripherally in the anterior layer of the superficial fascia, and deep toward the chest wall along the strands of fibrous tissue to the lymph vessels on the deep pectoral fascia. Sometimes a bursa is found behind the breast.

The deep pectoral fascia, like the deep cervical fascia, also splits into layers which enclose the pectoral muscles; the anterior layer covering the pectoralis major is attached to the clavicle, sternum, and is continuous with the deep fascia covering the rectus abdominus and external oblique and laterally with that covering the serratus magnus below and deltoid above. Between these muscles the fascia forms the floor of the axilla. The posterior layer encloses the pectoralis minor, forms the costacoracoid membrane, continues under the clavicle, enclosing the subclavius muscle, and is inserted into the subclavian groove. These various layers of the posterior part of the deep pectoral fascia are known as the clavipectoral fascia. Pus or collections of fluid between the pectoral muscles are thus usually directed toward the anterior border of the axilla. If such collections occur behind the pectoralis minor (and therefore posterior to the fascia) they point at the base of the axilla or up above the clavicle.

In making a dissection of the axilla, the following muscles are encountered: anteriorly, pectoralis major, pectoralis minor, clavipectoral fascia (costocoracoid membrane); posteriorly, subscapularis, teres major, latissimus dorsi, and serratus anterior. The blood supply of the beast is from (1) perforating branches of the internal mammary, (2) external mammary branches of the lateral thoracic, (3) intercostals; the veins empty into the axillary and internal mammary. In the radical operation the following vessels are encountered: superior thoracic, thoracoacromial, lateral thoracic, subscapular, and also branches of the internal mammary and the intercostals. The veins are the same as the arteries. The cephalic vein which lies in the groove between the deltoid muscle and pectoralis major and thus demarcates the two muscles is a guide to the first part of the axillary artery because it empties into the axillary vein which overlaps the artery. The axillary vein is completely bared in the operation. The nerves are anterior branches of the intercostal, intercostohumeral, the long thoracic which supplies the serratus anterior), and the thoracodorsal (which supplies the latissimus dorsi). Sometimes in paralysis of the serratus the scapula falls forward, forming the so-called winged scapula (scapulae alatae).

Physiology

The lymphatics begin with disconnected reticular lymph capillaries which ramify the breast, and a special areolar network surrounds the nipple. These empty into the large plexus which lies upon the deep pectoral fascia. Here the principal channels are as follows: Along the axillary border of the pectoralis major into the axillary nodes—these are the first to be involved from carcinoma in the most common site, upper outer quadrant of the breast. From these, the nodes along the axillary vein are involved, and finally the subclavicular and supraclavicular nodes. Behind the pectoralis major on and under the clavipectoral fascia are lymph vessels which follow the superior thoracic, thoracoacromial, and external mammary vessels. These terminate in small nodes behind the pectoralis major in the axillary nodes and in larger nodes of the lateral thoracic and internal mammary chain. The mesial part of the breast drains into the internal mammary nodes and thence to the anterior mediastinal group. There are communications between the pectoral lymph channels of the two breasts accounting for "cancer en cuirasse."

The breast is essentially a mass of glandular tissue—a specialized skin organ. It is composed of a number of lobes, approximately twelve to sixteen, separated by layers of connective and adipose tissue. Each lobe is composed of small glandular structures with acini that secrete milk and is therefore an independent compound alveolar gland in itself. These empty into ductules which in turn empty into the four or five main ducts that widen into ampullae and then become narrow before emerging in the nipple. Each lobe is thus composed of lobules separated by dense connective tissue (interlobular) which contains much adipose tissue. The intralobular connective tissue is much more cellular than the interlobular and contains fewer collagenous fibers and practically no fat. The interlobular connective tissue carries vessels, nerves, and lymphatics. The area around the nipple is pigmented. It is equipped with special sebaceous glands (glands of Montgomery) that secrete an oily substance. The nipple is easily everted, due to erectile tissue, permitting the infant to nurse. The breast is intimately connected with the pituitary gland and ovaries in its physiological function. In a developmental way the breast changes at three stages of life. First, the change that occurs with the onset of menstruation. The breasts enlarge due to glandular development (evolutionary stage). Then, with pregnancy, the so-called lactation hormone is secreted, causing the breasts to enlarge and develop still further, and with the delivery of the baby (third or fourth day post partum), a profuse flow of milk occurs (functional stage). The third stage is at the menopause, when the glands lose their functioning ability and the epithelium of the acini and, to a lesser extent, the ducts undergo an involutionary change with atrophy, so that the breasts become saggy and devoid of structure, hanging like empty sacks with a small amount of atrophied glandular tissue

in their dependent portions. The interstitial connective tissue becomes less cellular and the collagenous fibrils decrease. The framework becomes a homogeneous, finely granular mass. These changes are normal and physiological.

The tubular mammary gland peculiar to mammals is a modified apocrine gland (see Chapter 22). The nature of such glands which occupy an intermediate position between holocrine and merocrine glands is that a part of the cell or its cytoplasm is extruded with functional activity. The nucleus is left intact and soon the cell recovers. Thus the mammary gland is related to certain sweat glands (q.v. Chapter 16) as shown by the myoepithelial cells which are prominent near the excretory ducts. Indeed certain epithelial tumors and cysts of the breast also show this close relationship. The most characteristic expression of the secretory function of the glandular cells are the drops of fat which accumulate in the end of the cell protruding into the lumen and which pass out of the protoplasm, leaving a defect in the cell which is soon repaired. Whether or not these cells secrete a small amount during each menstrual cycle is not definitely known. Some women with strong hormonal stimulation (estrone and progesterone) do have a primitive colostrum-like secretion with each cycle. The changes which occur with menstruation are probably due to hyperemia and some edema of the interstitial connective tissue. Some observers believe that there is a cyclic hyperplasia in the ductule and acinar epithelium with desquamation, very much as the endometrial changes in the uterus, and therefore the breast goes through a cycle of cellular proliferation and desquamation giving rise to pain, swelling, and nodularity in the breast before menstruation and also swellings of the axillary nodes which are thought to be due to the presence of phagocytosed desquamated cells and debris carried by the lymphatics.

Malformations of the Breast

Some persons are born with malformations of the breasts. Normal variations in the size and shape of the breast are found. Frequently one is larger than the other. *Virginal hypertrophy* means unusually large breasts in adolescent girls or nulliparous young women which may attain such size that they become bothersome and embarrassing. It may involve one or both breasts, usually both. The enlargement is due to hypertrophy of all elements but chiefly the connnective and adipose tissue. The cause is not known but is said to be due to excessive estrogenic hormone stimulation. Occasionally surgeons are called upon to remove part of the breast tissue, rarely to perform a complete mastectomy. *Athelia* is the absence of nipples; the occurrence is rare. It is not pathological and does not lead to disease. However, it does lead to complications when pregnancy and lactation occur, because the milk is formed in the breast and has no exit. Surgeons sometimes make an opening in the breast. Retracted or small nipples are troublesome anomalies in the lactating breast. *Micromazia* is incomplete development. It means that the breast has never undergone proper development and is therefore useless for nursing. *Amazia* is the absence of the entire breast. *Polythelia* or supernumerary nipples are sometimes found. It is an atavistic tendency on the part of nature and reminds one of a sow or dog. The nipples may or may not be connected with breast tissue. In the event of the former, milk may be secreted from four to six nipples if one is nursed. Sometimes when they are in the axilla they are a source of annoyance. We have seen one case

where the only source of milk was in the abnormal nipple in the axilla, and and another case of eight nipples, four of which secreted milk. *Polymazia* means supernumerary breasts or nipples. *Hyperthelia* means the presence of supernumerary nipples with only two breasts. *Gynecomazia* means overgrowth of the breasts in the male. It is embarrassing but not pathological. It does not mean that the person is a hermaphrodite. This is a popular but erroneous belief. It is often associated with small testes and aspermatogenesis and not infrequently with impaired hepatic function, malnutrition, and chronic ulcerative colitis.

FIG. 144.—Hypertrophy of the breasts in a woman aged 28 years. A plastic operation was performed.

DISEASES OF THE BREAST

Diseases of the breast may be divided into those occurring in women under 40 years of age and those in women over 40. This is an arbitrary age and is based upon a study of diseases which are seen usually, *but by no means invariably*, in the age groups mentioned. At all ages functional disturbances occur. Abnormal secretions from the nipple are discussed later. Pain or mastodynia is usually caused by the cyclic turgescence which precedes menstruation. Often there is no assignable cause, especially in extremely nervous women. The complaint deserves careful

investigation. We have found that often *a proper support for pendulous* breasts which must be fashioned to fit each breast is a great help. Otherwise aspirin and local heat is useful.

Breast Lesions Which Occur Under 40 Years of Age.—

Mastitis (nonspecific)
1. Mastitis neonatorum
2. Mastitis of mumps
3. Mastitis of puberty
4. Lactation mastitis
5. Chronic plasma cell mastitis
6. Chronic mastitis, chronic cell mastitis

Tuberculosis of the breast
Actinomycosis and blastomycosis
Injuries and wounds, fat necrosis, and foreign bodies
Single and *multiple tumors and cysts*

MASTITIS.—

Mastitis Neonatorum.—Mastitis neonatorum is an inflammation of the breasts in the newborn. It is usually brought about by injudicious care of the baby. Many infants show a slight swelling and have a slight secretion from the breasts (colostrum) (it has been called "witch's milk") on the fifth or sixth day. This is thought to be due to the influence of estrogenic and mammotropic hormones derived by placental transmission. Menses sometimes occur also. Uninformed and superstitious women are apt to squeeze or traumatize the infant's breast, causing *subsequent infection.*

Mastitis of Mumps.—Mastitis of mumps is an unusual complication which usually subsides without abscess formation.

Mastitis of Puberty.—Mastitis of puberty may be due *to trauma* or "caking" of the breast. The latter is due to coagulation of "colostrum," with subsequent injury, or, as in the case of lactation mastitis, "caking" may so lower local resistance that indigenous bacteria may become active. This occurs at the age of puberty in either sex. A good plan is the use of a soft pad for protection.

Lactation Mastitis.—Lactation mastitis is not uncommon. It has all of the signs and symptoms of an abscess (Chapter 5). Usually it occurs *in the first two to three weeks post partum. Some say* it is due to a fissure or crack in the nipple. Sometimes we see the condition ante partum. It is probably due to indigenous bacteria which grow because of a lowered local resistance instigated by "caking" *which traumatizes* the breast as any foreign body does. The "caking" in turn is due to an overabundance of milk. In recent experiments on dogs we found that breast tissue is much more susceptible to *Staphylococcus aureus* infection than the rest of the abdominal wall. There is swelling, excruciating pain, and the presence of a tender, hard lump in the breast. The patient has fever, malaise, and anorexia. The prevention of this painful complication of pregnancy consists of cleanliness, gentleness, and release of

milk pressure. Some advise boric acid wash for the baby's mouth and mother's nipple before each nursing. Others use ointments on the nipple on the theory that softening them prevents "cracking." It is perhaps better to use nothing at all or 70 per cent alcohol to "toughen" the nipple. When an inordinate supply of milk is present, gentle breast pumping is indicated to avoid caking. Should infection develop, it is best to wait until localization has occurred. Lactation may be stopped by the use of large doses of estrogen. Then radial incisions should be made similar to the spokes of a wheel. This is done to avoid cutting across the main ducts with subsequent fibroses and retention cyst formation.

Chronic Plasma Cell Mastitis.—Chronic plasma cell mastitis is rare. Because of its firmness and painlessness it is frequently diagnosed as carcinoma. It usually involves one breast. Mild signs of inflammation may be present and occasionally there is a watery or creamy discharge from the nipple. There is skin dimpling and nipple retraction with enlargement of the axillary nodes. The cause of the disease is unknown. It is thought to be due to extravasation of material from the ducts into the periductal tissue—essentially an irritation by fat of milk or colostrum. Other theories are that the lesion is due to fat necrosis caused by trauma, bacterial infection, or virus infection such as that seen in association with lymphopathia venereum. Decomposing fatty material is probably the exciting factor. Histologically the lesion may resemble fat necrosis in its later stages which is characterized by plasma cells, lymphocytes, giant cells, and epithelial hyperplasia. Fat necrosis thus may resemble the medullary type of adenocarcinoma. Plasma cell mastitis as seen histologically shows ulceration of normal epithelium of the ducts which is replaced with granulation tissue; for this reason it is also called mastitis obliterans; the formation of foreign body giant cells gives it the name pseudotuberculosis, and the periductal collections of plasma cells and other leucocytes give it the name plasma cell mastitis. Intraductal accumulations of colostrum, cells, and leucocytes may show the presence of an *associated diffuse comedomastitis resembling comedocarcinoma. The* gross lesion appears as a yellowish-brown discoloration of the mammary tissue often associated with abscess formation. Indeed a correct diag*nosis cannot be made without removing tissue for biopsy although it may* be strongly suspected, especially if there are many plasma cells in the circulating blood stream. The treatment is palliative and mild x-ray.

Chronic Mastitis, Chronic Cell Mastitis.—Chronic mastitis, chronic cell mastitis may resemble the plasma cell variety clinically but not microscopically. There is usually pain and axillary lymphadenopathy with a hard firm, mass occupying most of the breast. We have recently seen this in a young woman following radical mastectomy of the opposite breast for adenocarcinoma. The skin has the thickened pig-skin appearance; the cut section is white and firm with little fat and occasional cysts. Histologically there are small cysts of the acini and ducts and some hyper-

plasia of epithelium; the intralobular stroma is edematous with lymphocytic infiltration. The interlobular stroma shows lymphocytic infiltration also. Simple mastectomy may be necessary to make the diagnosis. If proved by biopsy, a breast support is all that is necessary.

TUBERCULOSIS OF THE BREAST.—Tuberculosis of the breast is also rare. The signs and symptoms are no different from those of tuberculosis elsewhere. The disease is secondary to tuberculosis elsewhere and usually asserts itself by a breast lump after pregnancy. There is lack of pain in the breasts. The axillary lymph glands are enlarged. Many draining sinuses arise. The treatment is directed against the general tuberculosis, of which this is secondary. In addition, mastectomy with axillary node excision is necessary. Often the ribs and cartilage are involved requiring their removal.

ACTINOMYCOSIS AND BLASTOMYCOSIS.—Actinomycosis and blastomycosis have been encountered in our clinic. The chronic draining sinuses, surrounded by scarred and indurated tissues, suggests the diagnosis, which is established by smears and tissue from biopsy. The lymph glands are not involved.

In early localized infections, mastectomy may effect a cure. Later, iodides are used internally and x-ray treatment locally.

INJURIES, WOUNDS, FAT NECROSIS, AND FOREIGN BODIES.—Almost every woman with a lump in her breast gives a history of some injury. Usually the blow was unnoticed until months or years later. It is very difficult to attach much significance to such stories. *Traumatic* fat necrosis may result from such contusions. While in themselves harmless the resulting nodule may resemble carcinoma clinically and biopsy may be necessary to make the proper diagnosis. Simple excision hematomas, wounds with milk fistulas, and foreign bodies, present no real difficulties in diagnosis or treatment. However, when in doubt biopsies should be done in addition to the routine care of such wounds.

Single and Multiple Tumors and Cysts.—In a woman under 40 years of age a single hard lump is probably a fibroadenoma. If the connective tissue elements predominate, it is known as an adenofibroma. These rarely become malignant, giving rise to low-grade carcinoma or sarcoma. Lewis has called attention to the relationship between fibroadenoma and granulosa-cell tumor of the ovary. This may be due to the hormonal stimulation of the breast but the modus operandi is not clear. If it is a single soft mass, it is probably a retention cyst, or galactocele. It is painless and *freely movable* in the tissues. The single hard tumor is solid and is composed of adult fibrous tissue and many normal glands, surrounded by a capsule. Therefore it is not fixed to adjacent tissues. A cyst transmits light and is softer than the solid tumors. It is an epithelial wall filled with straw-colored fluid or milk (galactocele). Multiple tumors are usually intracanalicular fibromyxomas. They are hard, freely movable and slightly painful, and are usually seen in young girls. These new

growths and cysts should be removed. A general anesthetic should be used, the growth or cyst, with the capsule, should be removed and then always submitted to the pathologist for microscopic examination. Multiple painful cysts which feel hard are sometimes found in young women; usually women with scanty menses and small breasts who are between 30-40 years and are nulliparous. If there is no bloody discharge from the nipple estrogenic hormone may give relief although the carcinogenic potentialities of estrogen in "susceptible breast must be borne in mind, even when given in small doses. For a continuation of this discussion see chronic cystic mastitis.

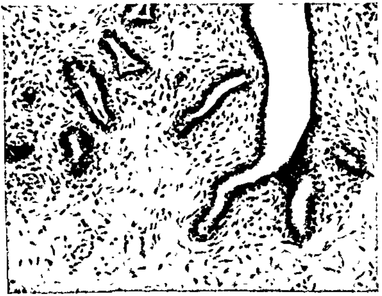

Fig. 145.—Pericanalicular fibromyxoma. The tumor was about the size of a small orange. It was removed from the breast of a girl aged 12 years. The connective tissue about the smaller ducts and canaliculi is involved.

Other benign tumors are simple encapsulated fibroma, encapsulated cystadenoma which is like a fibroadenoma except that the ducts are dilated into many small cysts, and lipoma. The nonencapsulated benign tumors are the pericanalicular fibromas which are probably more of a diffuse fibrous proliferation without duct destruction rather than new growths. They are seen commonly in the male breast. Benign duct papillomas which are small and do not cause cysts are important because they frequently cause bleeding from the nipple, q.v. Probing the ducts has been practiced so that the affected duct may be identified. This method is unsatisfactory as a rule because it often fails; the trauma induced by the probe is painful and may also cause bleeding. Any material obtained by the probe should be stained for cells. If no palpable tumor is present, a simple mastectomy may be necessary to rule out intraductal carcinoma. Warren has used the term adenocystoma to denote true intraductal papillary growths, commonly in the ampulla or larger ducts. It does not include the papillary projections of chronic

Fig. 146.—Intracanalicular fibromyxoma of the breast. The slitlike, epithelium-lined areas are the walls of invaginated canaliculi pushed inward by the tumor.

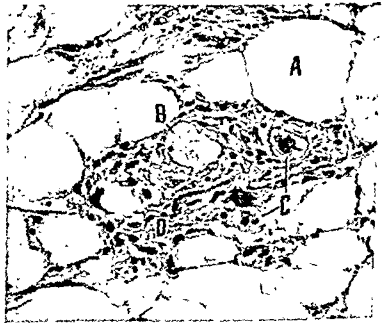

Fig. 147.—Fat necrosis in the breast. Medium-power photomicrograph showing the early changes in fat necrosis. This shows a clump of degenerating fat globules with fibrous tissue and phygocytic reaction. *A.* Unaffected fat globule. *B.* Degenerating fat globule. *C.* Giant cells. *D.* Young connective tissue cells. This lesion may resemble carcinoma clinically because it is a single tumor mass which is fixed in the tissues and is hard.

cystic mastitis. Adenocystoma is definitely a precancerous lesion. A rare type of cystic disease of the breast is due to apocrine type glands which become dilated and form multiple apocrine cysts or "butter cysts," so-called because of their contents which are thick and at times malodorous; also the term hidradenocystoma has been used. They are important because occasionally carcinoma arises in them. They should be removed. Microscopic studies show the cysts to be lined with apocrine type of epithelium. These cells have been called hidradenocytes and the term hidradenoma used to describe benign intraductal papilloma or papillomas in cysts containing these cells. Axillary apocrine glands as well as those which may be present in the breast adventitiously may undergo enlargement with each menstruation. *Malignant tumors* in young women are not rare. In the "under 40" group may be listed carcinoma which may be of the acute "inflammatory" type or sarcoma, usually fibrosarcoma, and rarely periductile myxoma or myosarcoma (cystic sarcoma, adenosarcoma), a cellular growth with much edema, hemorrhage, cyst formation, and necrosis. Radical excision of the breast and surrounding tissues, including all anatomical nodes, is the treatment of choice. In sarcoma, an x-ray study of the lungs and bones must be made first. If no metastases are present, radical surgery is necessary to effectuate a cure and this must be done early. A more complete discussion of malignant disease of the breast follows later in this chapter.

Breast Lesions Common After 40 Years of Age.—

- Plasma cell mastitis
- Tuberculosis
- Fungus infections
- New growths
  - Multiple tumors
  - Single tumor

PLASMA CELL MASTITIS.—Plasma-cell mastitis which has been described occurs in all age groups.

TUBERCULOSIS AND FUNGUS INFECTIONS.—Tuberculosis and fungus infections are not uncommon. These have been described in Chapters 7 and 8.

NEW GROWTHS, CHRONIC CYSTIC MASTITIS.—Far more frequent are new growths. These may be multiple. As we have seen in Chapter 15, multiple growths are usually benign. In addition, they may be painful. However, some women under 40 with every menstrual period have pain and small masses in their breasts which soon disappear. These are usually women who are unmarried and have scanty menses. In older women this same phenomenon is observed but the tender lumps persist. This condition has been called *chronic cystic mastitis,* although it is not a mastitis and is not always cystic. The entire problem is intimately related to hormonal imbalance or other constitutional agents as yet unknown. Perhaps local vascular factors play a role. The importance of the breast

changes which are grouped under this heading is their relation to carcinoma which is more than coincidental. We have noted that with each menstrual cycle there is stimulation and regression. This is shown histologically by hyperplasia of the periductal connective tissue and the epithelium (to a less extent) of the ducts which grow if pregnancy occurs. There is also increased vascularity with the estrus cycle. All of this is related to the ovarian hormones (estrogen, progesterone), the anterior pituitary hormones (galactogogue), adrenal-cortical hormone, and the testicular or androgenic hormones in the male. The exact relation-

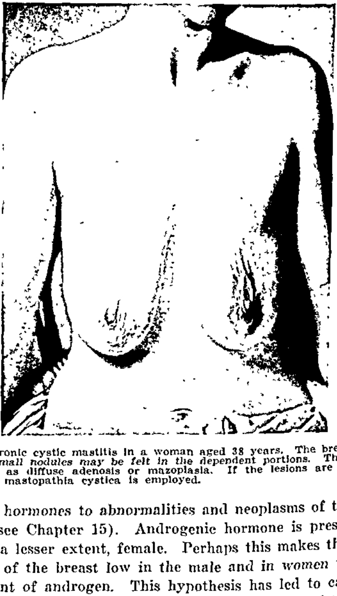

Fig. 148.—Chronic cystic mastitis in a woman aged 38 years. The breasts hang like empty sacks. Small nodules may be felt in the dependent portions. This condition is also referred to as diffuse adenosis or mazoplasia. If the lesions are predominantly cystic, the term mastopathia cystica is employed.

ship of these hormones to abnormalities and neoplasms of the breast is not known (see Chapter 15). Androgenic hormone is present in both male and, to a lesser extent, female. Perhaps this makes the incidence of carcinoma of the breast low in the male and in women who have a greater amount of androgen. This hypothesis has led to castration in the female with carcinoma of the breast and to the use of testosterone. There is no proof, however, that such is the case in the human being. During adolescence, chiefly because of estrogenic stimulation, the breast enlarges not only because of its connective tissue framework but also

because of its epithelial (glandular and ductal) elements. The menopause brings loss of weight generally and especially in the breasts. Interlobular fat disappears, the acini shrink, and their epithelial lining is practically desquamated. Nothing remains but dilated ducts, some periductal connective tissue, and an atrophic skeleton. This involutional change may give rise to functional aberrations and organic changes. The former may be manifested by pain and serous or milky or bloody discharge (which is practically always due to a papilloma and not vicarious menstruation) from the nipple. The organic changes may in-

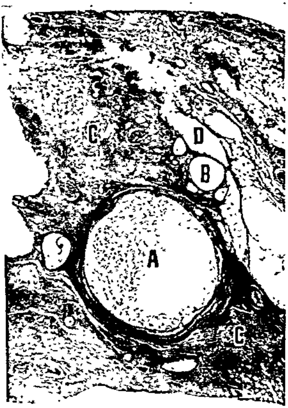

Fig. 149—Apocrine cysts of breast. Summar photograph (×10-75 diameters without use of microscope) of the breast with multiple apocrine cysts (butter cysts). *A.* Cyst. *B.* Smaller cyst with definite apocrine lining. *C.* Connective tissue. *D.* Flattened apocrine cyst with atrophic lining.

volve any or all of the breast elements. (1) The involutional process causes a reaction in the breast and soon the acini are surrounded by fibrous tissue which may proliferate in great abundance, completely enclosing or displacing the acini, which become involved in small fibrous scars, adenofibrosis. (2) Hyperplasia of glandular and ductal elements. Sometimes the hyperplasia is not regular, with variation in size and shape and staining reactions of the cells. This is more or less a precancerous lesion although there is no breaking through of the basement mem-

brane. If the hyperplasia involves mostly acini, the term adenosis or diffuse adenosis is applied and is comparable to adenosis of the thyroid gland. Small cystic areas may be present. This gives rise to the so-called "shotty" or "lumpy" breast and is known as *mazoplasia*, adenosis, sclerosing adenomatosis, or the *maladie cystic* of Reclus. (3) If the ductules are occluded partially and the acini incompletely, they are stimulated to secrete a primitive fluid, giving rise to many small cysts (blue-domed cysts of Bloodgood). This is known as the *cystiferous* breast or *mastopathia cystica*. Chronic cystic mastitis is usually seen in women with small or incompletely developed mammary glands. It is more common in those who have not borne children or who have had a relatively long period of sterility. In other words, women who bear children regularly develop a sort of immunity to the evolutionary and

Fig. 150.—Chronic cystic mastitis (cystiferous breast). Medium-power photomicrograph of a nodule in chronic cystic mastitis or Schimmelbusch's disease. *A*. Small cyst with hypertrophic lining. *B*. involuntary changes that occur with each pregnancy, so that fibrous tissue and epithelial reactions and epithelial desquamation are minimized when the menopause occurs. This is probably due to a control of the local resistance of the breast due to increased blood supply and functional activity initiated by the lactating and other hormones.

The diagnosis rests on the fact that there are multiple tumors, in both breasts, as a rule, which are freely movable and feel like a "bag of peanuts" and there is pain and tenderness in both breasts. It is difficult to distinguish between the cystiferous, the adenofibrotic, or the mazoplastic breast (often the three types occur simultaneously), but the breasts with epithelial hyperplasia (mazoplasia or adenosis) are more painful and more apt to be precancerous. However, the cystic type is

also dangerous because of the possibility of papillomatous growths within the cyst which may cause a bloody discharge from the nipple and not infrequently result in carcinoma. The percentage of carcinoma is said to be greater in a breast with chronic cystic mastitis than in the normal; therefore, the physician must be wary of any lumps. For this reason he prepares a chart for his patient. If he discovers anything unusual, he will note its size and position on the chart. In a month he will see the patient again. If the lesion is a chronic mastitis, the tumors will change in size and position. If a growth remains unchanged and has increased in size he will remove it for microscopic study. A liberal section of breast tissue which includes the nodule should be removed. If the microscopic features are those of epithelial hyperplasia with questionable neoplastic cells, then a simple mastectomy is indicated. Warren found that the breast cancer rate for women with chronic cystic mastitis and related lesions in the age group from 30 to 49 years is 11.7 times the rate for the Massachusetts normal female population; in the group over 50 years of age, 2.5 times as great; and the entire group 4.5 times as great. During the observation period before biopsies are deemed necessary local heat and anodynes may be given to relieve pain. *Estrogens are not indicated because they may incite epithelial proliferation and breast engorgement.* The androgens and progesterone may result in temporary improvement. Abolition of ovarian function by x-ray or surgical removal of the ovaries, though not advised by us, does relieve pain and sometimes causes a disappearance of nodularity.

Abnormal Discharge From the Nipple

Abnormal discharge from the nipple may be extremely varied. We have observed the following types: watery, milky, purulent, serous, serosangineous, bloody, and combinations of these. Watery discharge from the nipple is of no great importance. It is seen at all ages from adolescence to the menopause and is probably due to excessive hormonal stimulation. It may be artificially induced by stilbestrol or estrogenic hormone therapy. Milky discharge is not uncommon in infancy (colostrum), adolescence, before and after the lactation period in pregnancy, and associated with chronic mastitis. This galactorrhea is due to the early stages of lactation and is associated with hyperplasia of the acini. Later the ducts become filled with desquamated cells and stagnating secretion. Periductal inflammation, cysts, and hyperplasia of duct epithelium may follow. Purulent discharge is associated with lactation mastitis, plasma cell mastitis, rarely, tuberculosis, and fungus infections of the breast. Yellow serous discharge is observed in chronic cystic mastitis of any type, fat necrosis, or tuberculosis but may also be associated with functional derangements or benign intraductal papilloma. Serosanguineous or bloody discharge from the nipple is ominous. It is found in Paget's disease, intraductal papilloma, benign or malignant, proliferative papillary cystadenoma, adenocystoma, and all types of carcinoma

but chiefly in intraductal or cystadenocarcinoma and hemangioma. *A bloody discharge from the nipple demands surgical exploration.* It is almost always associated with an intraductal papilloma or carcinoma. The differential diagnosis can be made only by microscopic examination. Frequently there is no palpable breast tumor or lymph nodes in the axilla and yet extensive diffuse carcinoma may be present. It is our custom to do a simple mastectomy—the breast is quickly sliced and the slices placed on a long board. Each slice is inspected carefully and all suspicious lesions are cut out for frozen section. Should the lesions

Fig. 151.—Intracystic papilloma of breast. Medium-power photomicrograph of an intracystic papilloma. *A.* Fat. *B.* Wall of cyst. *C.* Remaining lumen. *D.* Papilloma. It is this type of lesion that may give rise to bleeding from the nipple. The lesion is serious because of its tendency to become carcinomatous.

be benign, no further surgery is done. If malignant, radical mastectomy is performed. Later the breast is hardened in formalin and cut with a meat slicer into thinner sections and the process of gross and microscopic section is repeated. By this routine we have found that (1) occasionally a small carcinoma has been overlooked and subsequent radical surgery was necessary; (2) when a palpable tumor has been biopsied or when several tumors have been removed for histological study an incorrect report of chronic cystic mastitis or adenosis has been made; then subsequent simple mastectomy done for persistent serosangineous discharge from the nipple has revealed early adenocarcinoma.

Carcinoma of the Breast

Etiology.—The cause of carcinoma is unknown. Recent experimental work has been summarized in Chapter 15. Some pertinent observations that are no doubt related to breast cancer should be reviewed.

Trauma.—Almost every woman with a lump in her breast attributes the lesion to an injury. There is no clinical or experimental proof that a single injury may cause carcinoma. However, *fat necrosis* may closely simulate carcinoma clinically and even microscopically. There may be a relationship to carcinoma in this way. Therefore the single, slightly painful hard lump should be removed for careful microscopic study.

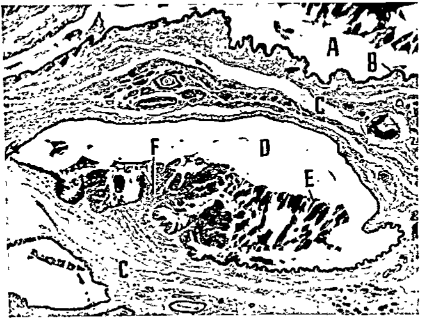

Fig. 152.—Intraductal papilloma of the breast. Low-power photomicrograph of an intraductal papilloma. *A.* Adjacent normal duct. *B.* Normal lining of duct. *C.* Connective tissue. *D.* Duct containing papilloma. *E.* Blood clot. *F.* Papilloma. This lesion is apt to give rise to carcinoma of the ductal variety (comedocarcinoma). Clinically it manifests itself by bleeding from the nipple. Bleeding is more apt to occur from an intraductal papilloma than from an intracystic papilloma because the latter would of necessity have to have communication with a duct in order for the blood to exude from the nipple.

Age.—No age is immune; the decade 50 to 60 years shows the largest number, with 40 to 50 years next. Although there are many studies to the contrary, our observations show a greater virulence of carcinoma in the young than in the old. In fact, the disease is not the same in its rapidity of growth, tendency to metastasize, and response to treatment in those over 70 years. Inflammatory carcinoma seen in the young is a deadly disease not amenable to any known therapy. Carcinoma after 70 years is slow and with the "strongly resisting" lymphatics the disease tends to remain local. Recurrences are not uncommon but they are usually accessible and may be removed. It is best to regard the disease as

deadly and equally amenable to treatment at all ages and to apply the *same radical treatment whenever the disease is encountered* if the patient can stand it.

Heredity.—Heredity plays a role. In 20 to 30 per cent of cases of mammary cancer there is probably an inherited susceptibility and in the female relatives of these women the incidence of breast cancer is said to be 3 times greater than in the general population. (See Chapter 15).

Fertility.—Carcinoma of the breast is seen more in women who have borne children because approximately two-thirds of the white women in this country bear children. However, *nulliparae are more prone* to develop cancer than those bearing children. The prognosis is the same in both groups.

Fig. 153.—Sclerosing adenomatosis of the breast (Summar photograph). *A.* Mass of adenomatous proliferation of the secretory acini *B.* Group of dilated ducts. *C.* An area of adipose tissue. This lesion is often mistaken for carcinoma, although it is benign and well localized as a rule. Actually it does not resemble carcinoma in all cases. However, if there has been much fibrosis, it may resemble carcinoma.

Lactation.—All experimental and clinical observation lends support to the belief that failure of the breast to perform its physiological function properly is the *most consistent apparent factor* in the genesis of cancer. The practice of "drying up the breast" and feeding the baby from the bottle is a deplorable fad which is a burden on the baby and a menace to the mother. We have recently operated upon a woman 49 years old with cancer of the breast who has borne fourteen children but she did not nurse any of them.

Estrogens *and the pituitary hormones are necessary* for the development of the mammary gland. Cancer occurs practically always in a breast that has undergone a certain degree of development. Presumably the estrogenic hormones produce an anatomical development sufficient to

allow the cancer process to manifest itself. Do estrogens act as carcinogenic agents? (1) In cancer strain mice the incidence of mammary cancer can be reduced to almost zero if the ovaries are extirpated in the very young (except the newborn)—this must be done before sexual maturity and the younger, the lower the incidence. (2) Cancer of the breast does not occur in male mice of a high cancer strain spontaneously. It does occur after the injection of large quantities of estrogen continued over long periods. Therefore, cancer of the breast in male mice of high cancer strain does not develop spontaneously because the hormone necessary for stimulation of the mammary gland is not present. (3) Diethylstilbestrol given to mice in (2) develop cancer. Therefore it is not the chemical per se but its effect physiologically that induces cancer; furthermore, cancer does not occur at the site of injection. (4) Incidence

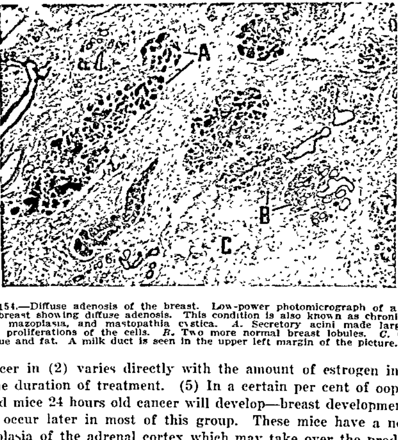

Fig. 154.—Diffuse adenosis of the breast. Low-power photomicrograph of a section from a breast showing diffuse adenosis. This condition is also known as chronic cystic mastitis, mazoplasia, and mastopathia cystica. *A*. Secretory acini made larger and solid by proliferations of the cells. *B*. of cancer in (2) varies directly with the amount of estrogen injected and the duration of treatment. (5) In a certain per cent of oophorectomized mice 24 hours old cancer will develop—breast development and estrus occur later in most of this group. These mice have a nodular hyperplasia of the adrenal cortex which may take over the production of estrogen. (6) Besides estrogenic stimulation, the "milk factor" (see Chapter 15) may play a role. (7) *Many clinical reports of cancer of the breast thought to be due to estrogenic therapy have been reported—none proved.* (8) We have observed many men with carcinoma of the prostate who have received enormous doses of diethylstilbestrol. The breasts become greatly enlarged. We have not seen any cases of carcinoma

of the breast nor have we found any such reports in the literature. Most of these men are in the "proper" age group. (9) In most women with cancer of the breast menopause has occurred. The luteal hormone is absent but not the follicular; therefore, estrogenic stimulation is *decreased.* Here the explanation has been a loss of ovarian control over normal growth and stability of tissue in the breast allowing other unknown substances with growth-stimulating properties to act. (10 Estrogenic stimulation has not produced mammary carcinoma in rabbits or monkeys. (11) Testosterone or progesterone administered at the same time that estrogen is given to susceptible mice does not prevent cancer from forming. (12) The essential feature of estrogenic cancer is the acceleration or the prolongation of the ripening and maturity in the

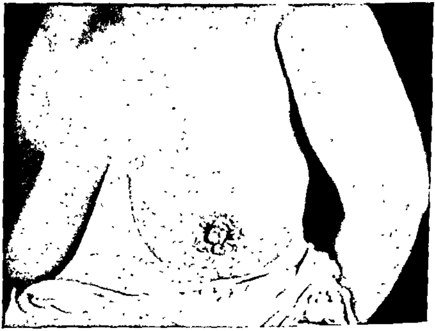

Fig. 155.—Large adenocarcinoma of the breast in a woman aged 48 years, with metastasis in the axillary glands but none in bones or lungs. The case was treated by pre- and postoperative x-ray therapy and radical resection.

mammary gland beyond physiological limits in mice. (13) Human mammary cancer may result from abnormally intense estrogenic stimulation during the adolescent period of mammary development or during a previous pregnancy; ovarian dysfunction in cyclic women resulting in relative hyperestrogenism over a period of years prior to the menopause (most of these have adenosis or cystiferous breasts); intense or continuous estrogenic stimulation at the time of the menopause (superimposed on the previous factors).

Summary: Experimental evidence shows a strong relationship between estrogenic stimulation and carcinoma of the breast, particularly in cancer strain mice. Estrogens in the human will cause an enlargement of the breasts when given in very large doses over a long period of time. The enlargement is due chiefly to an increased vascularity and

hyperplasia and hypertrophy of the connective tissue and, to a less extent, of the epithelial elements. Therefore there is a stimulation to growth of normal as well as to abnormal cells. As yet there is no definite proof that normal cells may be changed to cancer cells by estrogens in the *human being*—*estrogen therapy should be used cautiously* and if any breast abnormality exists it is perhaps better not to use the drug.

Pathology.—Various types of carcinoma occur in the breast. Adenocarcinoma is a mild form and more nearly resembles glandular architecture; medullary carcinoma, encephaloid carcinoma, and carcinoma simplex are soft cellular growths undergoing early necrosis; scirrhus carcinoma *is hard and fibrous, actually decreasing the size of the breast* (if the glands are involved they are small and hard); mucoid carcinoma shows a primitive secretion or mucoid degeneration; Paget's disease of the nipple may be a malignant dermatitis or duct carcinoma; a rapidly fatal variety is the acute inflammatory carcinoma of pregnancy. Duct cancer may occur at the beginning of the ducts (Paget's), at their termination, or along *their course (comedocarcinoma).*

Fig. 156.—Adenocarcinoma of the breast (medullary cancer). Note the scarcity of blood vessels, the small amount of stroma, and the variety of large malignant cells.

Ewing divides carcinoma of the breast based on anatomical features into (1) adenocarcinoma arising chiefly in cysts of ducts or sweat glands (apocrine); (2) duct carcinoma from the lining cells of ducts; (3) acinar carcinoma from the epithelium of the acini. *Subdivisions of these main* groups are mucoid carcinoma, fibrocarcinoma, and carcinosarcoma.

Paget's disease of the breast and of the vulva are similar. The resemblance to gland tissue has led to the opinion that the growths originate in the apocrine glands in the areola. Similar types of carcinoma have

of the breast nor have we found any such reports in the literature. Most of these men are in the "proper" age group. (9) In most women with cancer of the breast menopause has occurred. The luteal hormone is absent but not the follicular; therefore, estrogenic stimulation is *decreased*. Here the explanation has been a loss of ovarian control over normal growth and stability of tissue in the breast allowing other unknown substances with growth-stimulating properties to act. mammary gland beyond physiological limits in mice. (13) Human mammary cancer may result from abnormally intense estrogenic stimulation during the adolescent period of mammary development or during a previous pregnancy; ovarian dysfunction in cyclic women resulting in relative hyperestrogenism over a period of years prior to the menopause (most of these have adenosis or cystiferous breasts); intense or continuous estrogenic stimulation at the time of the menopause (superimposed on the previous factors).

Summary: Experimental evidence shows a strong relationship between estrogenic stimulation and carcinoma of the breast, particularly in cancer strain mice. Estrogens in the human will cause an enlargement of the breasts when given in very large doses over a long period of time. The enlargement is due chiefly to an increased vascularity and

largest single lymphatic plexus in the body, the disease has access to all the parietal tissue, accounting for the wide dissemination of skin nodules in some late cases of cancer of the breast.

Since centrifugal permeation of the fascial plexus has been proved, this process must also carry cancer cells to the periosteal lymphatics of the subcutaneous areas, where the fascia is attached directly to the bone. As lymphatics and veins always run along together, infiltration of the wall of the concomitant vein is a likely event, and subsequent extension to the bone may take place along the blood channels. The involvement of the femur on the same side as the cancerous breast before the opposite femur is involved is a result of this process. Cancer of the breast may spread:

1. By *infiltration* through tissue spaces surrounding the primary focus, with the production of a lump. This is a slow and limited process.
2. By *permeation* of small lymphatic vessels of the deep fascial plexus.
3. By *lymphatic embolism* to the axillary glands, first of the same side, and later of the opposite side.
4. By *blood embolism*, a rare but positive event.
5. By *finding a portal of entry to the great cavities of the body as in para-sternal* invasion of the thorax.

Fig 158.—Paget's disease of the nipple. The low power shows the downward growth of epithelial cells through the skin and subcutaneous tissue, and their invasion of a duct. The high power shows the large malignant Paget cells, which are characteristic of this lesion.

An unrecognized law of cancerous growth:

Every aggregation of carcinoma cells has a definite life cycle, and, after increasing in size for a varying period and at a varying rate, tends spontaneously to undergo degenerative and fibrotic changes. These changes extend from the center of the mass centrifugally to its periphery, lead to shrinkage, and *terminate in the replacement* of the aggregation of cancer cells by a fibrous scar.

A permeated lymphatic undergoes a series of changes due to its distention and rupture by cancer cells which fill it and to the inflammatory process that reults. In the end the original lymphatic is replaced by a solid thread of fibrous tissue from which

been reported in the axilla and around the anus—common sites for apocrine glands. Paget cells may be malignant apocrine gland cells. Other sites of origin may be as follows: (1) the ductal epithelium extending up the ducts and permeating the lymphatics draining the nipple. The lesion advances by intraepithelial growth to the nipple involving it and later neighboring ducts and connective tissue. The cells infiltrate centrifugally from a single primary source and are malignant from the beginning; (2) it is derived from stratified squamous epithelium. Although there is some dispute concerning its origin, many factors seem to point to its apocrine gland origin. The important fact is that the disease is not an "eczema" or dermatitis but it is a malignant disease of the breast requiring radical surgery. Eczemas do occur in both breasts in young persons; Paget's disease is practically always seen in one breast. Biopsy may be necessary to make the diagnosis.

Fig. 157.—Paget's disease of the nipple in a woman aged 40 years. Radical resection was performed.

Perhaps more important than the varieties of carcinoma is the method of its spread:

Handley's Hypothesis.—Repeated observations have proved that the first local spread of the carcinoma takes place by a rapid process termed "permeation" which consists of the growth of plugs of cancer cells along the lymphatic vessels of the breast rather than by the slow process of infiltration. Permeation equal in all directions is the "master process" of dissemination, for it penetrates small anastomotic lymphatics where the stream is too sluggish and the vessels too narrow for the passage of emboli of cancer cells.

As a result of the rich network of intramammary lymphatics and its numerous communications with other parts of the lymphatic system, the disease is able to pass early and easily to parts beyond the breast. Many of these lymphatics run directly back to the fascial plexus overlying the pectoralis major muscle. Since this is the

and the subserous fat, and the linea alba is penetrated by lymphatic vessels. Because it is possible to guard against invasion by this route by removing the "dangerous" portion of the anterior layer of the rectus sheath, abdominal recurrence has become relatively rare in recent years.

Other factors explained on Handley's hypothesis are: carcinoma of the breast rarely permeates below elbow or knee. For if equidistant on all sides, it would involve vital structures in the thorax and elsewhere, causing death.

The most common bone site is in the humerus, where the deltoid muscle is inserted, and the greater trochanter of the femur—the deep fascia is closest to the bones at these sites.

The vetebrae are involved by permeation along intercostal lymphatics involving dorsal nerve roots long before the vertebrae themselves are involved. This explains the severe pain before x-ray evidence of metastasis.

Permeation is equidistant in all directions. This explains the bad prognosis when axillary glands are involved. Mediastinal glands may also be involved.

Permeation is along the deep tubular lymphatics first. Along the deep fascia, then, there is retrograde involvement of the reticular lymphatics. The perilymphatic fibrosis set up by the cancer cells causes lymphatic obliteration which interferes with lymph drainage, producing edema late (cancer en cuirasse) or pigskin appearance early. It is unfortunate that there is permeation first, then fibrosis, rather than the reverse.

Metastasis may reach the abdomen by way of the rectus sheath (or deep fascia) up the ligamentum teres or falciform ligament of the liver, and into the porta hepatis, and then break through the liver capsule.

Carcinoma penetrates the chest wall and involves the pleura first, then the lungs.

Theoretically, all of the local cancer area can be removed. This may not prevent the growth in distant areas already permeated but does prevent any local recurrence.

Symptoms and Signs.—A single growth in one breast in a woman past 40 years old is carcinoma until proved otherwise. The classical symptoms and signs are

1. A single growth in one breast.
2. The growth is *painless.* Pain occurs only in *late* carcinoma.
3. It is fixed to the skin or surrounding tissue. This is elicited by moving the growth gently in a circular manner producing a slight tug on the skin.
4. Some retraction of the nipple (if the growth is near it).
5. A pigskin appearance over the growth due to blockage of the connecting lymphatics in the ligaments of Cooper.

These are the early symptoms and signs. Later there is large growth with fixation of the entire breast, enlargement of the axillary glands, *local ulceration, edema of one* or both breasts (cancer en cuirasse), pain in the breast (nerve invasion) and back (vertebral metastasis), extreme loss of weight, cachexia, metastasis to the lungs and liver, and ultimately death.

Prognosis.—From questionnaires sent to patients who had been operated upon for carcinoma of the breast in the Indiana University Hospitals, we may state that in all cases (early and late) our five-year cure is about 33 per cent; the *early ones, about* 67 per cent. However, a five-year cure does not mean a cure. It means the disease has been arrested for five years. Fifteen- or twenty-year cures would really reveal *cures.*

cancer cells have disappeared. This process has been named perilymphatic fibrosis. Thus, the carcinoma apparently heals in its central portions while spreading at its periphery.

Parasternal Invasion of the Thorax.—Simultaneous with invasion of the axillary glands there is an invasion of the glands of the internal mammary chain which lie behind the costal cartilages lateral to the sternal border. These glands do not lie in the range of operation and there are no clinical methods by which their condition can be determined. The failure of a well-planned operation for breast cancer is now most frequently explained by the unsuspected early invasion of the parasternal glands. (This usually manifests itself after a period of about three years but may not appear for as long as fourteen.) A study of scientifically planned operations has revealed "local and axillary recurrences to be reduced almost to zero and more than half the recurrences are found either as nodules at the inner ends of the upper intercostal spaces, or show themselves in the supraclavicular triangle, the glands of which are connected with the internal mammary chain." (Handley.)

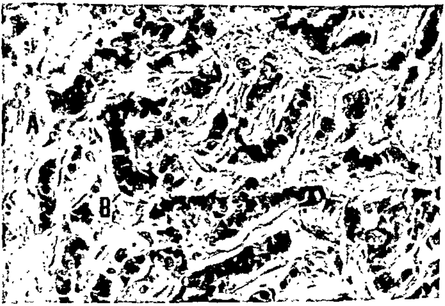

Fig. 159.—Scirrhus type carcinoma of breast.—Photomicrograph of scirrhus carcinoma of the breast. This might also be termed, a scirrhus type of carcinoma simplex with rows of cancer cells separated by connective tissue. This is the type that, as time goes on, becomes more and more filled with connective tissue and then the cancer cells become atrophic. In fact, the entire lesion becomes smaller so that it has been aptly said that this is one type of carcinoma of the breast in which, as it grows, the breast becomes smaller. Finally, the picture is one of scar tissue with a few cancer cells remaining in it. *A.* Connective tissue between the masses of cancer cells *B.* Linear arranged carcinoma cells.

The patient begins to complain of pain along the edge of the sternum on the side of the operation. Small nodules soon appear at the inner ends of the upper intercostal spaces. The skin becomes adherent to the nodules and ulceration follows. The tumor in the superior mediastinum causes dyspnea and dysphagia due to pressure on the trachea and bronchi and pressure on the recurrent laryngeal nerve and the esophagus. Pleural effusion and cardiac failure may supervene as terminal events. Autopsy shows a mass of growth filling the superior and anterior mediastinum and infiltrating the sternum.

Epigastric Invasion of the Abdomen.—The lower and inner margin of the breast reaches to within an inch of the ensiform cartilage, a region in which the body cavity is poorly defended against the attack of permeation. At the tip of the ensiform the linea alba is the only layer intervening between the permeated fascial lymphatic plexus

and the subserous fat, and the linea alba is penetrated by lymphatic vessels. Because it is possible to guard against invasion by this route by removing the "dangerous" portion of the anterior layer of the rectus sheath, abdominal recurrence has become relatively rare in recent years.

Other factors explained on Handley's hypothesis are: carcinoma of the breast rarely permeates below elbow or knee. For if equidistant on all sides, it would involve vital structures in the thorax and elsewhere, causing death.

The most common bone site is in the humerus, where the deltoid muscle is inserted, and the greater trochanter of the femur—the deep fascia is closest to the bones at these sites.

The vetebrae are involved by permeation along intercostal lymphatics involving dorsal nerve roots long before the vertebrae themselves are involved. This explains the severe pain before x-ray evidence of metastasis.

Permeation is equidistant in all directions. This explains the bad prognosis when axillary glands are involved. Mediastinal glands may also be involved.

Permeation is along the deep tubular lymphatics first. Along the deep fascia, then, there is retrograde involvement of the reticular lymphatics. The perilymphatic fibrosis set up by the cancer cells causes lymphatic obliteration which interferes with lymph drainage, producing edema late (cancer en cuirasse) or pigskin appearance early. It is unfortunate that there is permeation first, then fibrosis, rather than the reverse.

Metastasis may reach the abdomen by way of the rectus sheath (or deep fascia) up the ligamentum teres or falciform ligament of the liver, and into the porta hepatis, and then break through the liver capsule.

Carcinoma penetrates the chest wall and involves the pleura first, then the lungs.

Theoretically, all of the local cancer area can be removed. This may not prevent the growth in distant areas already permeated but does prevent any local recurrence.

Symptoms and Signs.—A single growth in one breast in a woman past 40 years old is carcinoma until proved otherwise. The classical symptoms and signs are

1. A single growth in one breast.
2. The growth is *painless*. Pain occurs only in *late* carcinoma.
3. It is fixed to the skin or surrounding tissue. This is elicited by moving the growth gently in a circular manner producing a slight tug on the skin.
4. Some retraction of the nipple (if the growth is near it).
5. A pigskin appearance over the growth due to blockage of the connecting lymphatics in the ligaments of Cooper.

These are the early symptoms and signs. Later there is large growth with fixation of the entire breast, enlargement of the axillary glands, *local ulceration, edema of one* or both breasts (cancer en cuirasse), pain in the breast (nerve invasion) and back (vertebral metastasis), extreme loss of weight, cachexia, metastasis to the lungs and liver, and ultimately death.

Prognosis.—From questionnaires sent to patients who had been operated upon for carcinoma of the breast in the Indiana University Hospitals, we may state that in all cases (early and late) our five-year cure is about 33 per cent; the *early ones, about* 67 per cent. However, a five-year cure does not mean a cure. It means the disease has been arrested for five years. Fifteen- or twenty-year cures would really reveal *cures.*

cancer cells have disappeared. This process has been named perilymphatic fibrosis. Thus, the carcinoma apparently heals in its central portions while spreading at its periphery.

Parasternal Invasion of the Thorax.—Simultaneous with invasion of the axillary glands there is an invasion of the glands of the internal mammary chain which lie behind the costal cartilages lateral to the sternal border. These glands do not lie in the range of operation and there are no clinical methods by which their condition can be determined. The failure of a well-planned operation for breast cancer is now most frequently explained by the unsuspected early invasion of the parasternal glands. (This usually manifests itself after a period of about three years but may not appear for as long as fourteen.) A study of scientifically planned operations has revealed "local and axillary recurrences to be reduced almost to zero and more than half the recurrences are found either as nodules at the inner ends of the upper intercostal spaces, or show themselves in the supraclavicular triangle, the glands of which are connected with the internal mammary chain." (Handley.)

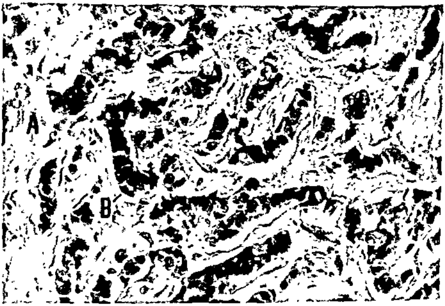

Fig. 159.—Scirrhus type carcinoma of breast.—Photomicrograph of scirrhus carcinoma of the breast. This might also be termed, a scirrhus type of carcinoma simplex with rows of cancer cells separated by connective tissue. This is the type that, as time goes on, becomes more and more filled with connective tissue and then the cancer cells become atrophic. In fact, the entire lesion becomes smaller so that it has been aptly said that this is one type of carcinoma of the breast in which, as it grows, the breast becomes smaller. Finally, the picture is one of scar tissue with a few cancer cells remaining in it. *A*. Connective tissue between the masses of cancer cells. *B*. Linear arranged carcinoma cells.

The patient begins to complain of pain along the edge of the sternum on the side of the operation. Small nodules soon appear at the inner ends of the upper intercostal spaces. The skin becomes adherent to the nodules and ulceration follows. The tumor in the superior mediastinum causes dyspnea and dysphagia due to pressure on the trachea and bronchi and pressure on the recurrent laryngeal nerve and the esophagus. Pleural effusion and cardiac failure may supervene as terminal events. Autopsy shows a mass of growth filling the superior and anterior mediastinum and infiltrating the sternum.

Epigastric Invasion of the Abdomen.—The lower and inner margin of the breast reaches to within an inch of the ensiform cartilage, a region in which the body cavity is poorly defended against the attack of permeation. At the tip of the ensiform the linea alba is the only layer intervening between the permeated fascial lymphatic plexus

of five years in Stage A are probably cured. Those in Stage C are apt to have late recurrences. Five-year cure should not be called a cure because *even in Stage A there may be ten-year recurrences* in 25 to 30 per cent.

The time elapsed since the onset is difficult to evaluate. Patients really do not know exactly when the lump began—they do know when they first discovered it. Therefore no patient should be refused surgery because of time or stage except in Stage E if the patient is in condition to stand radical surgery.

The prognosis of "inflammatory" carcinoma or cancer of the breast *occurring in gravid and puerperal women, "acute carcinosis,"* is extremely grave—we have not had a five-year cure by any method of treatment. Inflammatory cancer begins deep in the breast, spreads rapidly by the intramammary lymphatics, and is *usually well developed before it* is discovered. The inflammatory reaction is greater because the deep blood supply is prodigious. Mucoid carcinoma is less malignant as a rule than other types. Perhaps this is due to the fact that at least in some of these the mucin represents a primitive secretion showing a cell with some function and therefore a neoplasm which is less malignant.

It takes two to make the bargain in carcinoma—the "virulence" of the growth and the "resistance" of the patient. Therefore every case should be given the chance of cure if there is a remote possibility of cure.

Treatment.—Until the cause of cancer is known, prevention is impossible. *Perhaps the most important step in prevention is to urge every* child-bearing woman to nurse her baby. A full period of lactation with each pregnancy offers a degree of protection against cancer and its precursor in some cases—adenosis. *Another method of "protection"* is to avoid overstimulation with estrogenic hormones. Once the disease is present, early and complete removal offers the only means of cure. In *early cases the proportion of five-year cures may reach 70 per cent* or more. The patient with a tumor, even though it appears innocent, is advised by the physician that radical operation may be necessary. This gives the surgeon a free hand. He will remove the growth with the cautery or scalpel by the "nontransplantation" technique (see Chapter 15), if in doubt, and submit it for frozen section. If carcinoma is present, radical mastectomy must be done. We have seen in Chapter 15 that in carcinoma of the breast, the pectoral fascia, pectoral muscles, and axillary and supraclavicular nodes must be removed. The large area of skin removed often requires skin graft and the complete removal of muscles and fascia may lead to temporary restriction of motion. The arm may become edematous due to pressure on the axillary vein or pressure with resultant thrombosis and lymphatic obstruction. The treatment of this complication is discussed in Chapter 11. It is a mutilating procedure but not half so destructive locally or systemically as the carcinoma would be.

The fate of a woman with carcinoma is sealed when she comes to the doctor's office because he can procure an arrestment of the disease only if widespread metastasis has not occurred.

What happens to the patient that has nothing done? One out of four (25 per cent) will survive for five years but there will be practically no cures (one or two spontaneous cures have been reported by good authorities), whereas in the surgery group some will be cured. The scirrhus type is more apt to give a no-treatment five-year survival and also this variety may give the surgeon a false impression concerning the efficacy of five-year arrestment. What happens if x-ray and radium are used? The results will be similar to those when surgery is used, with surgery having a 3 per cent advantage. What does all this mean? Simply this: that no matter whether surgery or x-ray is used, the result depends upon the extent of the growth.

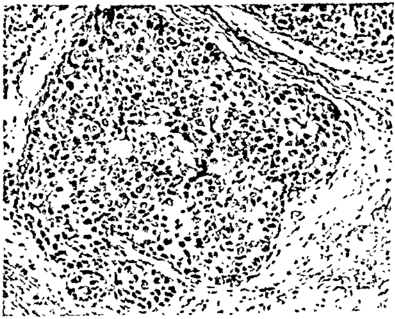

Fig. 160.—Diffuse duct-cell carcinoma of the breast. Also called comedo carcinoma, due to the cellular debris which may be expressed from the duct. The duct wall is greatly thickened and is replaced by malignant cells.

Perhaps the most important factor in prognosis is the stage of the disease at treatment. The Cancer Committee of the American College of Surgeons recommends the following classifications: Stage A—disease limited to the breast; Stage B—questionable involvement of axillary nodes; Stage C—axillary nodes involved; Stage D—Supraclavicular nodes involved; Stage E—Remote metastases present. Obviously the greatest number of the five-year cures will be in Stage A. Curability as well as survival time of patients not cured decreases in Stage B and more in Stage C as axillary lymph node metastases increases. Also local recurrence is more apt to occur in Stage C than in Stage A or B. Furthermore, patients living without clinical evidence of cancer at the end

C. Adair recommends postoperative x-ray treatment and uses the following dosage: If there is a moderate amount of axillary involvement, a total of 1,800 to 2,000 roentgens are used. If there is a large amount of axillary disease with cancer spread over as far as the costoclavicular ligament, 2,000 to 2,250 roentgens are employed (Stage D). The divided dose (Coutard) method is used. Enough should be given to control the lymphatic node spread but not enough to cause edema. Irradiation alone is used in some clinics. The results are *not as good* as in surgery alone or surgery with subsequent x-ray treatment mainly because the axillary nodes cannot be effectively destroyed, although some roentgenologists have obtained excellent results. We have used it as a palliative measure in late inoperable carcinoma (Stage E). It may be indicated in those who cannot stand surgery, although the effects of irradiation are not innocuous. In late, badly ulcerated, and infected carcinoma with general metastasis simple excision is done as a palliative and hygienic measure. It is also done occasionally in women over 75 years of age and those in poor general condition due to associated disease. Postoperative irradiation is used in this group (Stage E).

Other Methods of Treatment.—Bilateral oophorectomy or x-ray castration has been advocated as a complementary or supplementary procedure to radical mastectomy particularly in young women and the premenopausal group, those with acute inflammatory carcinoma (acute carcinosis), those who are pregnant or recently post partum, the more advanced cases with metastasis or recurrent lesions. The influence of estrogenic hormones has been reviewed in this chapter and in Chapter 15. In view of all available information, castration must be regarded as experimental and its merits as yet entirely unproved. We have used the procedure in the type of cases mentioned without any discernible benefit. Several reports of castration in the male with late carcinoma of the breast have been favorable—one states that results equal those of castration in carcinoma of the prostate.

Testosterone propionate has been used in late carcinoma in large doses —200 mg. daily for seven days and 25 mg. three times a week for ten weeks. Implantation of testosterone pellets subcutaneously has also been used. There are no toxic effects. A regression of the primary lesion and of soft parts metastasis and relief of pain does occur. If hypercalcemia is present, this may be aggravated. This therapy should be controlled by daily blood counts, serum calcium, serum phosphorus, alkaline phosphatase determinations, and urinalyses. It is also used postoperatively in doses of 200 mg. per week. There may be virilism, disturbed menstruation, or amenorrhea as a result of its use. We have used the drug in a small number of patients with advanced mammary cancer including two patients with pleural involvement. Our results have been good as to its temporary effect on the growth and relief of pain.

Carcinoma and Pregnancy.—We have reviewed this subject in Chapter 15. Our experience has been that the disease is not curable by any

There is much discussion concerning the relative merits of irradiation, surgery, or combinations. Early, complete, and radical surgery offers the best chance for cure. Reports are available to show that even a simple mastectomy (which we do not condone) will produce 70 to 80 per cent five-year cures or results as good as the radical procedure.

These cases probably have no axillary node involvement (Stage A) and since this cannot be accurately determined without a biopsy of the nodes, the operation of removing the breast or just the growth is dangerous and does not give the patient her best chance. Preoperative irradiation does not add any to the possibilities of cure. In fact, it delays the operation and in this way actually does harm. *Radical mastectomy is the best form*

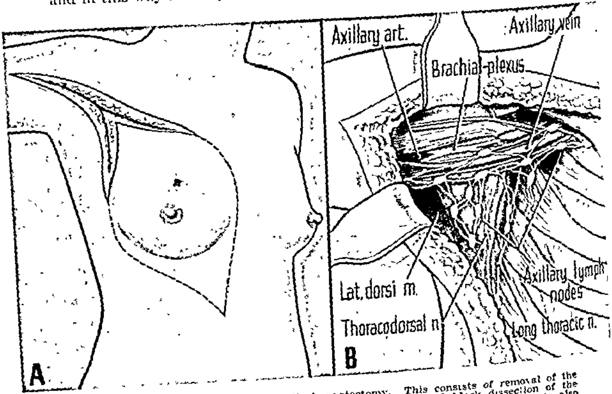

Fig. 161.—Diagram illustrating radical mastectomy. This consists of removal of the breast, the subcutaneous tissue and skin, fascia, muscles, and block dissection of the axillary lymph nodes. If necessary, dissection of the supraclavicular nodes is also carried out. The entire area should be removed in toto so that lymphatics will not be cut across. If sufficient skin remains, as may be the case in small breasts with a very small early lesion, primary closure may be done. If not, secondary skin graft will be necessary.

A. Skin incision. *B*. The pectoralis major and minor muscles and the costocoracoid membrane have been divided and pulled medially and downward to show the lymph nodes. The thoracoacromial artery and vein, long thoracic artery and vein, subscapular artery and vein have been tied and divided.

of treatment available for the cure of mammary cancer. The term radical means complete excision of the primary growth, its extention and its metatases insofar as is possible. This may necessitate (1) exploration of supraclavicular as well as axillary node basins; (2) resection of ribs and cartilages and intercostal muscles along with the pectorals; (3) excision of pleural spread; and (4) even lobectomy. This is as good as surgery plus postoperative irradiation in our hands for Stages A, B, and

Malignant Melanoma

Malignant melanoma of the breast has been reported in current literature and by Deaver and McFarland. It is extremely rare.

Neoplasms of the Male Breast

Chronic cystic mastitis occurs in the male breast in much the same variety as the female. Fibroadenoma and periductal fibroma is seen rarely. Cancer of the male breast is as malignant as in the female. It is usually seen at a later stage and therefore statistics show it to be even more "virulent" than in the female. It is treated by radical mastectomy. We have had good results in this group—five-year cures have been 75 per cent. Two of our patients were colored men.

form of therapy. We have used three methods of treatment: (1) radical mastectomy followed by supravaginal hysterectomy and bilateral salpingo-oophorectomy; (2) preoperative irradiation, radical mastectomy, and postoperative irradiation; (3) x-ray therapy alone. The effects of irradiation should be theoretically better because the speeded-up growth of cells stimulated by the development of the organ in which the cancer cells live are more susceptible to x-ray therapy. We are now in favor of radical mastectomy and postoperative irradiation—the pregnancy is not disturbed. Castration is not done but testoresone is given.

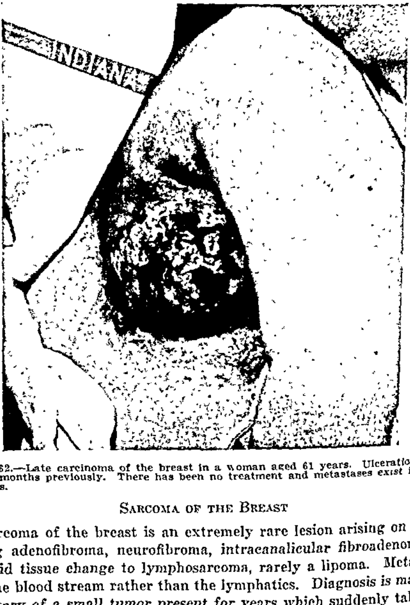

Fig. 162.—Late carcinoma of the breast in a woman aged 61 years. Ulceration began eighteen months previously. There has been no treatment and metastases exist in bones and lungs.

Sarcoma of the Breast

Sarcoma of the breast is an extremely rare lesion arising on a pre-existing adenofibroma, neurofibroma, intracanalicular fibroadenoma, or lymphoid tissue change to lymphosarcoma, rarely a lipoma. Metastasis is by the blood stream rather than the lymphatics. Diagnosis is made on the history of a small tumor present for years which suddenly takes on very rapid growth, reaching an enormous size. Biopsy is the only sure way of making the diagnosis. Treatment is by radical mastectomy except in the case of lymphosarcoma which is amenable to x-ray therapy.

system is a closed one, lined by endothelium. This tissue, therefore, is of great importance in health and disease—perhaps often the initial seat of disease, with subsequent perivascular involvement.

Blood vessels are are largest as they enter or leave the heart and smallest at the periphery. Lymph vessels increase in size as they approach the veins, into which they empty. The entire system is a closed one although there is some dispute about the spleen, bone marrow, and lymph nodes. The splenic pulp spaces are thought to be the only connection between arteries and veins in this organ (see Chapter 22). Sinusoidal types of vessels are found in the bone marrow and thickened meshworks of capillaries in lymph nodes. It is true, however, that in both of the latter sites blood cells and lymphocytes must enter the circulation by breaking through the walls of vessels.

THE HEART

The mammalian heart pursues a complex course in its development. Like the primitive blood vessels, the heart starts with an interna endothelial tube which becomes the essential component of the endocardium and an external mesodermal layer which gives rise to the myocardium and epicardium.

The heart and its covering, the pericardium, occupy the inferior portion of the mediastinum. It is well protected and cannot be approached with aspiration needle except in a small area which is not overlaid with lung. This area is to the left of the xyphoid cartilage, close to the sternum, in the fourth and fifth interspaces. A few years ago the surgeon did not dare to operate upon the heart. Today he is called upon to suture stab wounds of the heart and thereby prevent fatal hemorrhage.

Congenital Malformations of the Heart and Major Vessels

Congenital cardiovascular defects occur in about 1 per cent of all births. Abbott classified congenital heart disease into three main groups:

Group I. Acyanotic group. No abnormal communications between the right and left side of the heart. Incidence about 25 per cent of cardiac anomalies.

a. Coarctation of the aorta—8%
b. Anomalies of the aortic arch—2%
c. Aortic stenosis—2%
d. Anomalies of semilunar cusps—5%
e. Pericardial defects—2%
f. Displacements of the heart—2%

Group II. Cyanose tardive group. These patients have arteriovenous shunts with arterial blood entering the pulmonary circulation. Cyanosis usually not present but a transient reversal flow may produce cyanosis. Incidence 50% of cardiac anomalies.

a. Patent ductus arteriosus—13%
b. Defects of auricular septum—20%
c. Defects of ventricular septum—17%

Group III. Cyanosis is a prominent feature. Incidence 25% of cardiac anomalies.

a. Tetrology of Fallot—12%
b. Tricuspid atresia—1%
c. Pure pulmonary stenosis—1%
d. Transposition of great vessels—2%
e. Eisenmenger's complex—5%
f. Persistent truncus arteriosus—1%
g. Complete septal defects—1%
(cor triloculare and biloculare)

Chapter 17

CIRCULATORY SYSTEM

Embryology and Anatomy

Early authorities stated that blood vessels and blood cells arise from a tissue termed the angioblast (His). It is probably mesodermal in origin and is first seen in the yolk sac. The solid cords of angioblast soon hollow out, leaving the peripheral cells as the endothelium and the inner cells as the primitive blood cells or mesoameboids (Minot). Authorities do not agree as to the exact origin of the vascular system. Many observers state that the first blood vessels and cells appear in the area vasculosa which surrounds the embryonic body and overlies the cavity of the yolk sac. The peripheral mesenchyme which spreads out between the ectoderm and mesoderm gives rise to groups of basophil cells (blood islands) connected by strands of elongated cells which are transformed into endothelial tubes. The endothelium secretes a liquid, the primitive blood plasma which fills the tubes. The first blood elements or primitive blood cells are free mesenchymal cells. These free cells in the connective tissue become the first red and white blood cells; others become the endothelium of blood vessels; still others form lymph vessels. These primitive vessels join to make the endothelial lining of arteries, veins, and lymphatics. Larger vessels acquire outer layers. Capillaries do not, so that they may have a free exchange with the connective tissue spaces. Thus from connective tissue the real vascular tissue of the body originates. By the union of isolated endothelial spaces a vascular network results, which ultimately permeates the entire body. This growth is by budding or sprouting with the formation of loops and off-shoots. The primitive vessels may serve as arteries or veins (Sabin), probably accounting for many capillary malformations (hemangioma), anomalous vessels, and enlargements of organs. Vessels have three coats. The outer coat *(adventitia)* is composed of connective tissue. Sympathetic nerves are found here. They come off at various levels from peripheral nerves—except in the larger vessels, where the nerves come directly from the sympathetic ganglia. The blood supply to the vessel (vasa vasorum and vasa venorum) is found in the adventitia. The vaso vasorum originate from near-by small arteries and form a dense capillary network in the adventitia, penetrating to the media. In veins they penetrate to the intima and the veins of these vessels open into the lumen of the vessels they drain. Lymphatics are also present in the larger vessels. The middle coat *(media)* is formed of muscle and elastic fibers in varying proportion in the different sized vessels. The large arteries have little muscle, mostly elastic tissue, allowing for great expansion. The arterioles have a relatively thick muscle coat to permit vasomotor control. The capillaries have no muscular coat but have Rouget cells which are probably modified endothelial cells and are capable of causing contraction. The boundary between the tunica intima and media is formed by the internal elastic membrane which is most noticeable in medium sized arteries. The inner coat *(intima)* consists of endothelium and prevails throughout the vascular system.

It has been estimated by Krogh that there are over 700 capillaries per cubic millimeter in normal human muscle. He states that these capillaries placed end on end would extend over 100,000 kilometers (62,000 miles). Since the muscles constitute only about 40 per cent of the weight of the healthy adult body, it would be conservative to estimate the total length of all the capillaries in the rest of the body at 38,000 miles; therefore we may conclude that there are more than 100,000 miles of blood capillaries. The lymphatic capillaries and vessels are almost as numerous. The entire

Fig. 163.—Congenital anomalies of the heart and great vessels. Case of an adult with a thrombotic occlusion of both pulmonary arteries secondary to severe pulmonary atherosclerosis which, in turn, was probably sequential to a patent interventricular septum. Associated anomalies were a right-sided arch of the aorta and an anomalous left subclavian artery springing from the descending portion of the aorta and resulting in a vascular ring about the esophagus and trachea. There were also a patent foramen ovale and a large interventricular septal defect. Cyanosis and dyspnea increased abruptly twenty-eight days before death probably due to the fact that the pressure in the pulmonary artery equalled that of the systemic pressure and much blood flowed back from right to left not being oxygenated. Two other factors contributed to the cyanosis and dyspnea: (1) anoxic anoxemia due to the vascular ring compression of the trachea and chronic interstitial pneumonia; (2) bilateral pulmonary artery thrombosis.

This was a case of a man 45 years of age who complained of being short of breath and of having heart trouble since early childhood. When brought to the hospital he was extremely ill, deeply cyanotic, and dyspneic. His blood pressure was 105 systolic, 70 diastolic. The circulation time, arm-to-lung, was 7.5 seconds. The arm-to-tongue time was prolonged to 27 seconds. Normal should be between 9 and 16 seconds. The venous pressure was 17 cm. of water. Five electrocardiograms taken during his hospital course showed a left axis deviation with delayed intraventricular conduction and auricular fibrillation.

1. Photograph taken from behind, showing the greatly dilated pulmonary artery and the posterior portion of the vascular ring. *AA*, arch of aorta; *DA*, descending aorta; *DP*, dilated branches of left pulmonary artery; *E*, esophagus; *LA*, ligamentum arteriosum; *LPA*, left pulmonary artery; *LS*, left subclavian artery; *RS*, right subclavian artery; *SD*, saccular dilatation; *T*, trachea; *LL*, left lung.

2. Photograph of the specimen from the front with a window cut in the right ventricle to demonstrate the septal defeat. The pulmonary artery has been opened and reflected to show the great dilatation present and the occluding mass on the left pulmonary artery. Note the greatly thickened right ventricular wall.

ASA, ascending aorta; *DB*, dilated branches of *LPA*; *E*, esophagus; *IS*, interventricular septal defect; *LL*, left lung; *LPA*, left pulmonary artery; *O*, occluding thrombus in *LPA*; *PA*, pulmonary artery (greatly dilated); *RC*, right common carotid artery; *RPA*, right pulmonary artery; *RS*, right subclavian artery; *RV*, right ventricle; *T*, trachea.

3. Photograph of the specimen taken from above and behind. It shows the vascular ring above the esophagus and trachea. It shows also the greatly dilated and thrombosed left pulmonary artery and its branches. *AA*, arch of aorta; *DA*, descending aorta; *DB*, dilated branches of pulmonary artery; *E*, esophagus; *LA*, ligamentum arteriosum; *LC*, left common carotid artery; *LL*, left lung; *LPA*, left pulmonary artery; *LS*, left subclavian artery; *RC*, right common carotid artery; *RS*, right subclavian artery; *SD*, saccular dilatation; *T*, trachea.

circulation must be balanced by an equal volume of unsaturated blood entering the pulmonary circulation. A unilateral shunt would lead to a diminishing blood volume in either pulmonary or the systemic circulation.

Incomplete Development of Heart and Great Vessels

Rarely there is a tendency toward doubling due to incomplete fusion of the paired primordia. More common congenital abnormalities are an incomplete ventricular septum due to a faulty development of the septum membranaceum and persistent foramen ovale due to improper fusion of the septum primum and secundum. *Arey states that the latter occurs* in one out of every four individuals, but actual mingling of blood or inconvenience to the individual is unusual because the communication is small or because septal folds are pressed together during atrial contraction, acting as a valve. When the opening is large, there is intermingling of blood, causing cyanosis—"blue baby." Valvular anomalies occur in the atrioventricular and semilunar valves.

Due to the extensive work of Taussig, many other types of teratologic and congenital defects and deformities have been described and their clinical features studied. Operations for their relief have been devised by Blalock, Gross, Crafoord, Fauteux, Potts, and many others. Some of these procedures, while still in the experimental stage, are very promising.

Patent interventricular septa have been partially repaired by Murray as follows:

> A strip of fascia lata about ¾ inch wide was secured. A silk suture was attached on one end and this was threaded on a straight sewing needle four inches long. At a point slightly to the right of the descending branch of the left coronary just distal to the annulus fibrosis the reversed needle was passed through the anterior wall of the heart and then through the posterior wall. The suture was anchored to the epicardium.

Tricuspid atresia has been benefited by aortic-pulmonary anastomosis. *The physical findings are identical with those of the tetralogy of* Fallot except that there are (1) left axis deviation in the electrocardiogram (the only lesion that produces cyanosis and has this); (2) hypertrophy of the left ventricle; (3) hypoplasia of the right ventricle by x-ray studies.

When pulmonary stenosis involves the pulmonary valve itself (about 10 per cent) rather than the pulmonary conus (which is the site in over 90 per cent of the cases), a valvulotome may be inserted through an incision in the wall of the right ventricle and used to divide the pulmonary valves.

Methods Used in the Diagnosis of Various Types of Congenital Cardiac Anomalies

Symptoms and Signs.—The importance of murmurs and their connotations are different in adults and children. In children the appear-

Formerly anomalies of the heart and its major vessels were not amenable to surgical aid. Such is not the case now, although many abnormalities are not yet within the realm of surgical attack. The following discussion will consist of first a review of experimental and clinical work on the rarer types and second the more common varieties. In all kinds there are apt to be associated anomalies in the heart and elsewhere.

Abnormal Positions of the Heart and Great Vessels

Ectopia Cordis.—Ectopia cordis is a protrusion of the heart through an opening in the thoracic wall. This anomaly may cause serious circulatory phenomena due to lack of restraint of the normal heart. Usually only a thin layer of skin covers the heart and sometimes even this is absent (see Chapter 20—Celomic Cavity). The treatment consists of the formation of skin flaps in the latter instance. Cartilage grafts from the eighth and ninth costal cartilages may be used to bridge the defect in the upper sternum and ribs.

Dextrocardia.—Dextrocardia is a transposition of the heart and its vessels. It may be associated with no other anomalies and it may cause no symptoms. However, it is often seen with a general inversion of all the viscera. This is known as *situs inversus totalis* or *situs inversus viscerum*. This abnormality is, in turn, not infrequently accompanied by an agenesis of the accessory nasal sinuses and maldevelopment of the bronchi and the pancreas. The Kartagener syndrome includes situs inversus, bronchiectasis, and sinusitis. However, fibrocystic disease of the pancreas and gall bladder disease, including atresia of the bile ducts (in two of our cases) have also been found often to be noncoincidental.

Complete Transposition of Aorta and Pulmonary Artery.—Complete transposiiton of the aorta and the pulmonary artery if "uncorrected" is incompatible with life. The aorta arises from the ventricle which receives systemic venous blood, and the pulmonary artery arises from the ventricle receiving oxygenated blood. Thus the left ventricle pumps blood through the pulmonary artery to the lungs and this blood returns by way of the pulmonary veins to the left auricle. The right ventricle propels blood into the aorta, while the right auricle receives impure blood from the systemic veins. Usually there are associated septal defects or other abnormalities so that some oxygenated blood goes into the systemic circulation, permitting survival. Attempts have been made experimentally to correct the "uncorrected" condition by anastomosing the pulmonary vein to the superior vena cava, or by producing an interatrial septal defect. The latter operation might also be useful in mitral stenosis as observed in patients with a mitral stenosis associated with a patent foramen ovale (Lutembacher syndrome). In "uncorrected" transposition, it must be taken into consideration in shunts which are created that the volume of oxygenated blood shunted into the systemic

measures 20 volumes per cent. That is 20 volumes in each 100 c.c. of arterial blood. With the catheter in the right atrium, the sample of blood (mixed venous blood) shows 15 volumes per cent or 15 c.c. of oxygen in each 100 c.c. of venous blood. The total oxygen consumption as tested is 300 c.c. per minute. Thus, 5 c.c. of oxygen is taken up by the tissues per 100 c.c. of blood. The patient consumes 300 c.c. of oxygen per minute. Three hundred divided by five will give the units of 100 c.c. of blood flowing from the aorta (since aorta and femoral artery oxygen content are about the same) to the right atrium, or the *total systemic blood flow;* in this case, 60 units of 100 c.c. or 6,000 c.c. per minute.

In the lungs the oxygen goes into the blood instead of out of it. If the catheter tip is placed in the pulmonary artery, the blood sample may show 15 volumes per cent and that from the femoral artery, 20 volumes per cent (and this is practically the same as in the pulmonary vein). Thus 5 c.c. of oxygen has been added to each 100 c.c. of blood flowing through the lungs. The *pulmonary flow in each case is*

$$\frac{300}{20 - 15} \times 0.1 = 6 \text{ liters per minute.}$$

The volume of flow through single, one-direction shunts may be estimated by calculation of the difference between the pulmonary and peripheral flows. If there is a shunt in both directions more complicated formulas are needed.

The ratio of the effective pulmonary blood flow to the total systemic flow determines the degree of oxygen saturation in arterial blood.

The *pulmonary capillary flow* is determined by a method involving the equilibration of carbon dioxide with pulmonary capillary blood, sampling carbon dioxide content in alveolar air, and determination of carbon dioxide production. By comparing pulmonary artery with pulmonary capillary flow, the flow through the collateral vessels or through an artificial or congenital ductus arteriosus may be estimated (Bing).

The standard exercise test compares ratios of oxygen consumption to respiratory minute volume during rest and exercise. Normally oxygen consumption increases from rest to exercise. In conditions where the pulmonary flow is fixed (for example, pulmonary stenosis) the ratio usually declines.

The *oximeter* is an instrument which measures the oxygen saturation in peripheral arterial blood by means of a photoelectric cell attached to the pinna of the ear. It can be used in connection with the exercise test and is also useful in differentiating anoxemia due to venous-arterial shunts from deficient arterial saturation due to oxygen absorption difficulties resulting from pulmonary disease. In the latter case oxygen solution rises within one minute to full saturation when 100 per cent oxygen is inhaled. In shunts the time required will be much longer, and full saturation is rarely obtained.

ance of a murmur may suggest an abnormality, but the heart is too small, the blood pressure too low, and the chest wall too thin for the murmur to be of specific diagnostic aid. Useful diagnostic signs are unusual murmurs and thrills, cyanosis, clubbing of fingers, and alteration in size, shape, and position of the heart.

X-ray and Fluoroscopy.—X-ray and fluoroscopy frequently help make the diagnosis in conjunction with the information derived from the symptoms and signs.

Angiocardiography.—Angiocardiography is the visualization of the heart and great vessels with opaque media. This method may be briefly summarized as follows: (1) The patient is given a small capsule of one of the barbiturates. (2) The heart rate and blood pressure are determined. (3) The patient is tested for sensitivity to Diodrast, a brand of iopracyl, and if sensitivity is present, antihistamine drugs may be used or the drug may be employed in weaker concentration. (4) Decholin sodium solution, 5 c.c., is added to 20 c.c. of physiological saline and injected into an arm vein with the arm elevated to 45 degrees. The interval between the beginning of the injection and the onset of the bitter taste is measured by a stopwatch. This gives the arm-to-tongue circulation time and if less than 10 seconds the lung circulation time will be short—3 to 4 seconds. (5) To obtain arm-to-lung circulation time, 0.5 c.c. of ether is added to 20 c.c. of physiological saline and injected. The interval between the time of injection and the detection of ether on the patient's breath is the arm-to-lung circulation time. (6) The approximate time of opacification of the right ventricle and pulmonary arterial line and of the left ventricle and aorta is obtained by deducting one second from the arm-to-lung and the arm-to-tongue circulation times. (7) A concentration solution of Diodrast (a brand of iopracyl), 70 per cent by weight/volume, usually about 40 c.c. for adults, is injected. The duration of injection should be between 1½ to 2 seconds.

An added test is the combined use of angiocardiography and electrocardiography which permits synchronization of the various waves with the actual visualization of the heart.

Physiological Studies.—The most useful are catheterization of the heart, measurement of pulmonary capillary flow, a standard exercise test, and oximetry.

Venous catheterization gives much information. The position of the catheter should be followed by the use of the fluoroscope. Blood samples and blood pressures are obtained by means of the catheter from the cardiac cavities, blood vessels coursing to and from the heart, and from a peripheral artery. The volume of blood flowing through the pulmonary artery (pulmonary artery flow), the intracardiac shunt, and the systemic blood flow may be calculated by the Fick principle from the oxygen content of the blood samples (see Chapter 13): Oxygen in the femoral artery

Pulmonary Stenosis or Atresia and Associated Defects

These anomalies result in a decreased volume of blood to the lungs for oxygenation. The result is cyanosis due to the anoxemia and compensatory polycythemia—the "blue baby." We shall see in Chapter 19 that cyanosis is due to the presence of reduced hemoglobin in the circulating blood. When venous blood is shunted into the arterial tree, cyanosis results. Cyanosis is dependent not only on the volume of blood going to the lungs for oxygenation but also on the height of the hemoglobin (less than 5 grams of reduced hemoglobin will not produce clinical cyanosis; therefore, the hemoglobin must be higher than 5 grams), the volume of

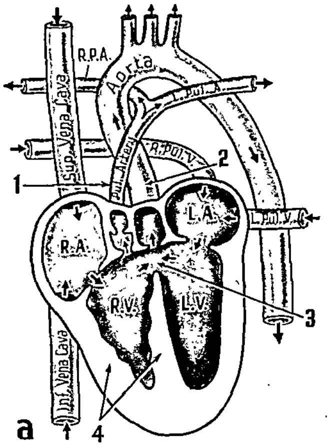

Fig. 164a.—Tetrology of Fallot. The four features of the tetrology of Fallot are (1) pulmonary stenosis, (2) dextroposition of the aorta, (3) a patent interventricular septum or at least an intraventricular septal defect, and (4) right ventricular hypertrophy. The arrows show the course of the circulation in the tetrology of Fallot.

R.A., Right auricle; *R.V.*, right ventricle; *L.A.*, left auricle; *L.V.*, left ventricle; *R.P.A.*, right pulmonary artery.

Note that the dextroposition of the aorta permits it to receive blood from both ventricles. Blood reaches the right auricle through the vena cavae and then it goes from the right auricle to the right ventricle. Then part of the blood goes through the narrow pulmonary artery and part directly into the aorta. The small volume of blood going through the pulmonary artery is oxygenated and returned to the left auricle and thence to the left ventricle. Blood from the left ventricle and some from the right ventricle is propelled into the aorta from which it is distributed throughout the body.

TABLE XIII

CHARACTERISTIC DATA EXPECTED FROM CATHETERIZATION OF THE HEART IN VARIOUS CONDITIONS
(Modified from Burchell and others: Proc. Staff Meet., Mayo Clin., 1948.)

	PRESSURES		OXYGEN CONTENT OF BLOOD		
	RIGHT VENTRICLE	PULMONARY ARTERY	RIGHT ATRIUM	RIGHT VENTRICLE	PULMONARY ARTERY
Normal	25/2	25/8	Equals venae cavae	Equals right atrium + *or* – 0.5%	Equals right ventricle
Cardiac disease					
Atrial septal defect	Slight increase	Slight increase	Increase over venae cavae	Like right atrium	Like right ventricle
Ventricular septal defect	Normal or increased	Normal or increased	Normal	Exceeds right atrium	Equals right ventricle
Patent ductus arteriosus	Normal or increased	Normal or increased	Normal	Normal	Exceeds right ventricle
Tetralogy of Fallot	Increased	Diminished	Lower than normal	Equals or exceeds right atrium	Equals right ventricle
Eisenmenger complex	Increased	Increased due to arteriolar changes in pulmonary vessels	Normal	Exceeds right atrium	Exceeds right ventricle
Pulmonary stenosis without septal defects	Greatly increased	Greatly diminished	Normal	Equals right atrium	Equals right ventricle
Essential pulmonary hypertension	Increased	Increased	Normal	Equals right atrium	Equals right ventricle

Some additional information *concerning various* congenital anomalies of the heart is as follows:

Tetralogy of Fallot.—The pulmonary artery flow is decreased. Collateral circulation is marked to the lung. The intracardiac shunt is from right to left. The exercise test shows a fall in oxygen consumed per liter of ventilation and a decline in peripheral arterial oxygen saturation. Breathing pure oxygen test. Peripheral arterial saturation rises over several minutes and full saturation is not reached.

Ventricular Septal Defect.—Exercise test—oxygen consumed per liter of ventilation increases and oxygen saturation of peripheral blood falls.

Patent Ductus Arteriosus.—Exercise test—oxygen consumed per liter of ventilation and oxygen saturation in peripheral blood remains constant.

Eisenmenger Complex.—The intracardiac shunt is from right to left due to increased resistance in pulmonary vascular bed.

Miscellaneous Data.—On a number of occasions the aorta has been catheterized through a patent ductus arteriosus. Many times in catheterizations of the heart anomalous pulmonary venous drainage is encountered. These anomalous veins may drain into the superior vena cava or the innominate veins; rarely, also into the inferior vena cava. The diagnosis is made by having the catheter enter the pulmonary vein directly from the superior vena cava and by finding a high oxygen content in the blood taken from the systemic vein. A pulmonary stenosis with an intact ventricular septum but with an atrial septal defect may be diagnosed as an entity. Sometimes in pulmonary stenosis without septal defects there is a marked increased pressure in the right ventricle which may exceed radial or brachial artery systolic pressure.

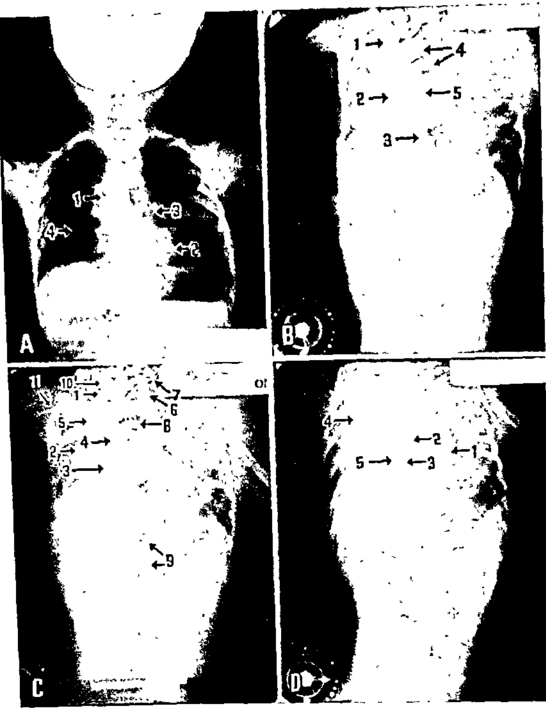

Fig 164b — A Plain posteroanterior roentgenogram of heart with barium swallow showing dextraposed ascending aorta (*1*), elevated apex (*2*), diminutive main pulmonary artery salient (*3*), and reduced peripheral pulmonary arterial markings in the lungs (*4*)

B Left anterior oblique angiocardiogram one second after injection of 70 per cent Diodrast showing opacification of superior vena cava (*1*), right atrium and right ventricle (*2*), inferior vena cava (*3*), simultaneous filling of overriding aorta and pulmonary arteries (*4*), and slight spill of dye through the high interventricular septal defect into left ventricle (*5*).

C. Left anterior oblique angiocardiogram at three-second interval. Superior vena cava (*1*), right auricle (*2*), right ventricle (*3*), stenotic infundibulum of right ventricle (*4*), aorta (*5*), left common carotid (*6*), left subclavian artery (*7*), poststenotic left dilatation of pulmonary artery (*8*), arteries to abdominal viscera (*9*), innominate artery (*10*), right subclavian artery (*11*).

venous blood shunted into the systemic circulation, the rate of utilization of oxygen by the peripheral tissues, and the extent of the aeration of blood in the lungs. The latter is obviously of great importance and depends on the vital capacity, the rate of blood flow through the lungs, the partial pressure of the oxygen in the inspired air, and specific pulmonary factors. Lundsgaard and van Slyke showed that these specific factors ("a" factors) are noted in cases of polycythemia. In such cases secondary changes occurred in the lungs of such a nature that not all the blood passing through the lungs was in effective contact with the oxygen in the alveoli. This is proved by the fact that in almost all cases of polycythemia, cyanosis may be improved by the prolonged inhalation of oxygen.

If the volume of blood going to the lungs is diminished, cyanosis results. In pulmonary atresia, in which the circulation to the lungs is by way of the ductus arteriosus, the closure of the ductus results in death. The diminished volume of blood to the lungs is seen in the following types of anomalies.

1. Single ventricle with a rudimentary outlet chamber. Usually the aorta arises from the common ventricle and is of good size; the pulmonary artery arises from the rudimentary outlet chamber and is small. Cyanosis results. If the vessels are transposed, a large volume of blood goes to the lungs for oxygenation and a smaller volume to the systemic circulation. Under such circumstances there will be no cyanosis but symptoms like those of coarctation which will be described later.

2. Truncus arteriosus. If the pulmonary arteries are given off directly from the aorta or heart, there is no cyanosis. If they fail to arise from the heart or connect with the aorta and the circulation to the lungs is by way of the bronchial arteries, a smaller volume of blood reaches the lungs and cyanosis results.

3. Tetralogy of Fallot. This consists of pulmonary stenosis, dextroposition of the aorta, interventricular septal defect, and right ventricular hypertrophy. The pulmonary stenosis consists of a narrowing of the pulmonary orifice and the pulmonary conus of the right ventricle. The aorta rises from the left ventricle and partially overrides the right ventricle; the aortic septum cannot meet the ventricular septum, and therefore, there is a high septal defect. It is difficult for blood to be expelled from the right ventricle due to the stenosis of the pulmonary artery, and, therefore, the right ventricle hypertrophies. The aorta receives blood from both ventricles. The ductus and foramen ovale are closed. A large volume of blood is returned to the right atrium and ventricle and a lesser amount to the left side of the heart.

4. Complete pulmonary atresia is compatible with life only if the ductus arteriosus remains open or the bronchial arteries establish sufficient collateral circulation.

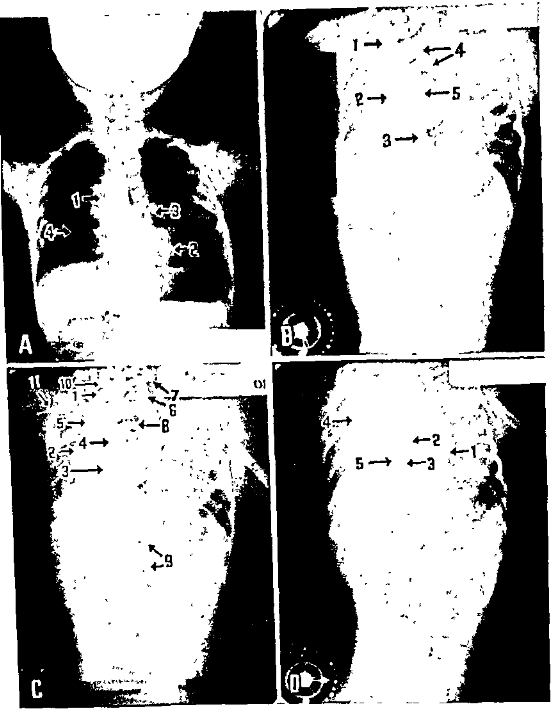

Fig. 164b—A Plain posteroanterior roentgenogram of heart with barium swallow showing dextraposed ascending aorta (1), elevated apex (2), diminutive main pulmonary artery salient (3), and reduced peripheral pulmonary arterial markings in the lungs (4)

B. Left anterior oblique angiocardiogram one second after injection of 70 per cent Diodrast showing opacification of superior vena cava (1), right atrium and right ventricle (2), inferior vena cava (3), simultaneous filling of overriding aorta and pulmonary arteries (4), and slight spill of dye through the high interventricular septal defect into left ventricle (5).

C. Left anterior oblique angiocardiogram at three-second interval. Superior vena cava (1), right auricle (2), right ventricle (3), stenotic infundibulum of right ventricle (4), aorta (5), left common carotid (6), left subclavian artery (7), poststenotic left dilatation of pulmonary artery (8), arteries to abdominal viscera (9), innominate artery (10), right subclavian artery (11).

D. Left anterior oblique angiocardiogram at seven seconds. Pulmonary veins (1), left atrium (2), left ventricle (3), reopacified aorta from left ventricle (4), interventricular septum (5).

5. Complete transposition of the great vessels. In this anomaly there is complete transposition of the great vessels as previously described. The pulmonary artery arises from the left ventricle and the aorta from the right ventricle. Blood goes to the lungs from the left ventricle through the pulmonary artery and is returned to the left auricle by the pulmonary veins. The right ventricle sends blood through the aorta to the

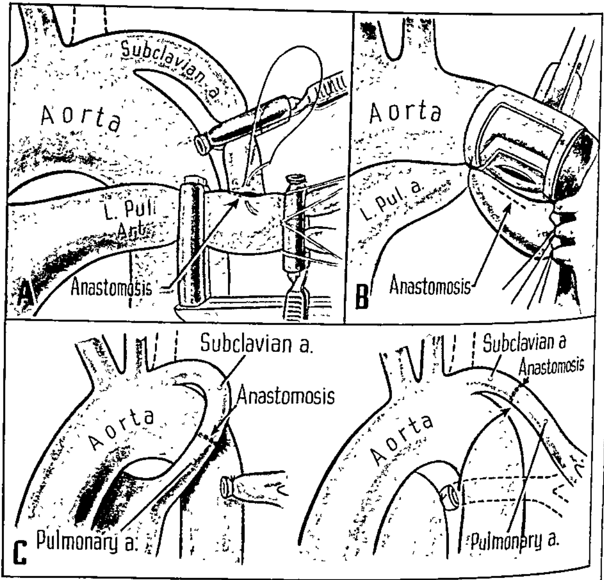

Fig. 165.—The treatment of pulmonary stenosis. Diagrams illustrating various operations which are designed to increase the pulmonary blood flow. The shunt as originally devised by Blalock and Taussig consists of anastomosing the subclavian artery with the pulmonary artery on the left side. In dextropositions of the aorta the innominate artery may be used. *A.* The anastomosis is made end to side as illustrated in the diagram. *B.* The Potts method of producing an artificial ductus arteriosus by anastomosing the aorta with the pulmonary artery with the use of the ingenious Potts clamp. A variation of this is the anastomosis of the pulmonary artery and the ascending aorta. *C.* Other methods employed in shunting the systemic blood into the pulmonary circulation. A branch of the pulmonary artery may be divided and the proximal end anastomosed to the proximal end of the subclavian artery, or the distal end of one pulmonary artery may be anastomosed to the proximal end of the subclavian artery. These are a few of the variations of the methods employed in supplying the lungs with sufficient blood by using one of the larger arteries of the systemic circulation; in other words, producing an artificial ductus arteriosus.

systemic circulation and this is returned to the right atrium via the venae cavae. Thus there is really a transposition of the pulmonary artery and the aorta but not of the vena cava or pulmonary veins. Oxygenated blood has a difficult time in reaching the systemic circulation. Indeed this would not be possible unless there were associated septal defects (auricular, ventricular, or both) or other abnormalities (patent ductus arteriosus, partial transposition of great veins). Recently Blalock and Hanlon have created auricular septal defects surgically and performed anastomosis between the subclavian and pulmonary arteries.

6. Tetralogy of Fallot of the Eisenmenger type. There is dextroposition of the aorta, interventricular septal defect, large right ventricle, and normal or increased size rather than stenosis of the infundibulum and pulmonary valve and artery. Cyanosis is said to be due to secondary changes in the pulmonary vascular bed or the alveolar plexuses, or, due to the increased pressure in the pulmonary circulation, more impure blood may be shunted from the left to the right ventricle. Surgery is not indicated in the Eisenmenger type.

7. Aortic atresia causes difficulty in pumping blood to the systemic circulation. Moreover, most of the blood reaching the systemic system is pumped through the ductus arteriosus before it has been to the lungs for oxygenation.

When there is an inadequate flow of blood to the lungs, surgery may be used to "short-circuit" around the obstruction. The clinical diagnosis, according to Taussig, rests upon three important features: (1) x-ray evidence that the pulmonary artery is small, (2) clinical and roentgenological evidence of absence of congestion in the lung fields, (3) absence of visible pulsation in the lung fields as observed under the fluoroscope. The typical case of the tetralogy of Fallot is not difficult to diagnose. In borderline cases of persistent cyanosis surgery is indicated, and if there is doubt, Blalock advises that the pressure in the pulmonary artery may be measured by using a needle and water manometer. Usually the pressure will be 150 to 240 mm. of water. If the pressure is more than 300 mm. of water, the operation is unnecessary. Because this approaches aortic pressure and usually indicates an absence of the ventricular septum, blood would not flow into the pulmonary artery in such cases. If, however, the systemic arterial pressure is higher, a shunt may be created even with pulmonary artery pressures of 500-600 mm. of water.

The operation seeks to divert blood from one of the major systemic arteries to one of the pulmonary arteries. Usually the approach is on the right side where the innominate artery is located. If the aorta descends on the right, the innominate will be on the left. Many surgeons prefer the left side in left aortic arch and the right side in right aortic arch, preferring the subclavian if possible. By exposing the innominate, the subclavian, common carotid, or innominate may be used, depending

on the existing inadequacy of the flow of blood to the lungs and the sizes of the available vessels. By this method an artificial ductus arteriosus is made and in the tetralogy of Fallot some of the blood which is pumped into the aorta will reach the lungs through the artificial ductus and thereby the left ventricle will receive more blood, better oxygenated, and the right side of the heart will receive less.

The results have been encouraging according to Blalock. There has been an increase in oxygen content of the arterial blood, a decrease in the oxygen capacity, an increase in the oxygen saturation of the arterial blood, a decrease in the red blood cell count, a diminution of the hemoglobin and the hematocrit reading, a decrease in the patient's disability, and an improvement in the patient's ability to exercise. The immediate mortality rate is 23 per cent. The arteries may be anastomosed in the following ways: end to side; the proximal end of the systemic artery with the distal end of a pulmonary artery (the blood pressure in the pulmonary artery is less than half that in the systemic due to low peripheral resistance; the flow of blood depends upon the relative pressure between the systemic and pulmonary circulations); the proximal end of the subclavian or common carotid with the divided proximal end of the pulmonary arteries to an upper lobe of one of the lungs; the side of the aorta with the left pulmonary artery; the side of the aorta to the side of the main pulmonary artery. Potts, Smith, and Gibson anastomose the pulmonary artery to the aorta by means of special clamps. If the patient has pronounced polycythemia, some blood loss (about 1 per cent of body weight) is helpful. Surgery is not indicated in cor biloculare, cor triloculare, persistent truncus arteriosus, and Eisenmenger's complex.

Aortic Arch Anomalies

Most textbooks of embryology, pathology, and anatomy mention the occurrence of abnormal developments in the aorta and its branches. Fig. 166 shows the embryological development. Recently Gross, Blalock, Crafoord, and others have shown the importance of recognizing these malformations so that surgical treatment may be instituted. The following is a classification of the more common types of aortic arch anomalies as listed by Gross.*

Classification of Aortic Arch Anomalies With Notes on Diagnosis and Treatment

I. Right Aortic Arch.—
   A. Situs inversus viscerum—usually no symptoms.
   B. Right aortic arch without inversion.
      1. Anterior type—Arch is anterior to the trachea. Descending aorta is right sided. Rare anomaly.
      2. Posterior type—Arch passes to the left behind esophagus. Descending aorta courses to the right or normal left side position.
         a. Right aortic arch in which the left subclavian artery arises last from the arch and crosses behind the esophagus may produce dysphagia by pressure of left subclavian posteriorly. This could be divided.

*Gross and Ware: Surg., Gynec. & Obst., 1946.

Aortic Arch Anomalies

Most textbooks of embryology, pathology, and anatomy mention the occurrence of abnormal developments in the aorta and its branches. Fig. 166 shows the embryological development. Recently Gross, Blalock, Crafoord, and others have shown the importance of recognizing these malformations so that surgical treatment may be instituted. The following is a classification of the more common types of aortic arch anomalies as listed by Gross.*

Classification of Aortic Arch Anomalies With Notes on Diagnosis and Treatment

I. Right Aortic Arch.—
- A. Situs inversus viscerum—usually no symptoms.
- B. *Right aortic arch without inversion.*
  1. Anterior type—Arch is anterior to the trachea. Descending aorta is right sided. Rare anomaly.
  2. Posterior type—Arch passes to the left behind esophagus. Descending aorta courses to the right or normal left side position.
     a. Right aortic arch in which the left subclavian artery arises last from the arch and crosses behind the esophagus may produce dysphagia by pressure of left subclavian posteriorly. This could be divided.

*Gross and Ware: Surg., Gynec. & Obst., 1946.

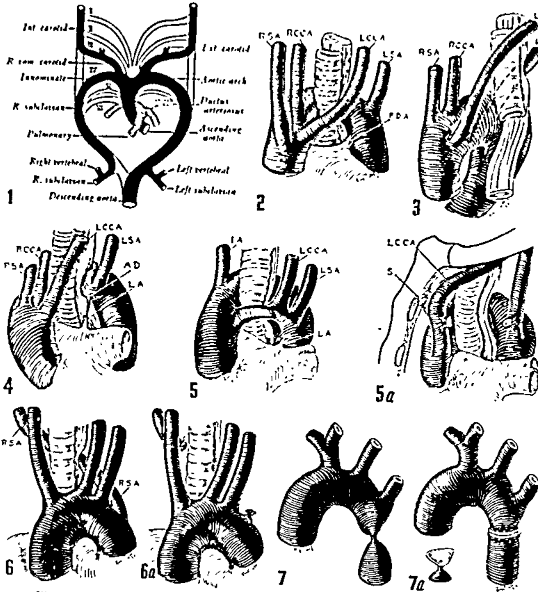

Fig. 166.—Anomalies of the aortic arch. *1* is a diagram showing the transformation of the human aortic arches. The scheme in the ventral view is shown with all vessels spread to the same plane. (Redrawn from Arey; modified from Congdon.) *2* is a diagram of a right aortic arch with no vessel from the arch crossing behind the esophagus. Left common carotid artery compressing the front of the trachea. Pulmonary artery drawn tightly against the trachea by the ductus arteriosus. *LCCA*, Left common carotid artery, *LSA*, left subclavian artery; *PDA*, patent ductus arteriosus; *RCCA*, right common carotid artery; *RSA*, right subclavian artery. *3* is a diagram of a right aortic arch with left subclavian artery arising last from the arch and crossing behind the esophagus. *LCCA*, Left common carotid artery; *LSA*, left subclavian artery. *RCCA*, right common carotid artery; *RSA*, right subclavian artery. *4* is a diagram of a right aortic arch with persistent left aortic diverticulum giving rise to the left subclavian artery and the ligamentum arteriosum. Frequently the aortic diverticulum is longer than is indicated in this diagram. *AD*, Aortic diverticulum; *LA*, ligamentum arteriosum; *LCCA*, left common carotid artery; *LSA*, left subclavian artery; *RCCA*, right common carotid artery; *RSA*, right subclavian artery. *5* is a diagram of a left double aortic arch. The ascending aorta divides into two limbs which subsequently join and form the descending aorta. The esophagus and trachea are compressed. *5a* shows a method of surgical treatment. The ligamentum arteriosum has been divided to allow the pulmonary artery to fall forward. The anterior or left limb of the double arch has been severed between the origins of the left common carotid artery and the left subclavian artery. The left common carotid artery is then tacked to the back of the sternum to keep it off of the trachea. *6* shows an anamolous right subclavian artery which arises from the left side of the aortic arch and presses on the posterior wall of the esophagus. *RSA*, right subclavian artery. *6a* shows a method of surgical treatment for the dysphagia. The subclavian artery has been divided and esophageal pressure thereby has been relieved. *7* is a diagram illustrating coarctation of the aorta with a high degree of constriction and obstruction just beyond the origin of the left subclavian artery. *7a* shows a method of treatment by the excision of the narrow segment and end-to-end suture of the aorta. Inset shows the excised portion possessing a very small lumen. (Diagrams slightly modified from Gross, R. E., and Ware, P. F.: Surg., Gynec. & Obst. 83: 435, 1946.)

b. Right aortic arch in which no vessel arising from the arch crosses the midline posterior to the esophagus. A vessel may pass in front of the trachea. The left common carotid may pass in front of the trachea and compress it. The left subclavian and left common carotid may arise from a left innominate. The pulmonary artery is pulled back against the trachea due to the posteriorly displaced arch and the resultant pull on the ligamentum arteriosum (or patent ductus arteriosus). Rarely it may be necessary to divide the compressing left common carotid or the ligamentum arteriosum (or patent ductus arteriosus).

c. Right aortic arch with a persistent left aortic diverticulum giving origin to the left subclavian artery and ligamentum arteriosum. The important part of this anomaly is the aortic diverticulum which is an outpocketing of the distal part of the arch and which gives rise to the left subclavian artery and to the ductus arteriosus (or the ligamentum arteriosum). If the aortic diverticulum presses on the esophagus and interferes with swallowing, it could be removed and the first part of the subclavian excised.

II. Double Aortic Arch.—The originally paired dorsal aortae may persist as a double aorta or double arch such as is found normally in reptiles (Arey). The ascending aorta thus splits into two limbs which join to form the descending aorta. Between the two limbs lay the esophagus and trachea or only the latter. There are two types.

A. Partially obliterated double aortic arch.—The anterior or left arch persists as a cord, whereas the posterior one or right arch carries the blood.

B. Completely patent double aortic arch.—Both the anterior and posterior limbs are patent. Usually the posterior one is much the larger. This anomaly may produce pressure on the trachea or esophagus or both and there may result dysphagia; stridor may occur and persist. Barium meal may show esophageal pressure; the air shadow in the trachea may show deformity, or Lipiodol may be used as a spray or instilled with the bronchoscope to visualize the trachea. If symptoms are severe, surgical relief may be instituted. The posterior and usually the larger arch cannot be attacked surgically. The anterior (left) and usually the smaller may be divided between ligatures and other anomalous vessels moved aside and held in place with sutures through the adventitia of these vessels and sutured to the chest wall (Gross).

III. *Anomalous Right Subclavian Artery.*—Arises from the left side of a normal aortic arch and crosses the midline, compressing the esophagus from behind, then coming to a normal exit from the right thoracic cage. It may also run in front of the trachea or between the trachea and esophagus. Rarely this anomaly gives rise to dysphagia or respiratory distress. The dysphagia has been called dysphagia lusoria (Bayford) from *lusus naturae* (a freak of nature). Surgery may provide relief by a division of the offending subclavian. Due to the good collateral circulation which communicates with the second and third part of the subclavian and with the axillary artery, the first part of the subclavian may be divided without impairment of circulation to the arm.

IV. *Patent Ductus Arteriosus.*—During fetal life the ductus forms a by pass from the pulmonary artery to the aorta, thus avoiding the inactive lungs. Normally the ductus closes during the neonatal period (first two weeks of life) but sometimes it remains patent (about 1 per cent after the first year of life). Should this anomaly persist, blood is shunted from the aorta into the pulmonary artery. Depending on the size of the ductus, 45 to 75 per cent of the blood pumped by the left ventricle is shunted. Since this blood has just been through the

lungs for oxygenation and has returned to the left auricle by the pulmonary veins, this is a useless circuit. That portion of the blood in the aorta which is not shunted goes to the rest of the body and is returned to the right atrium by the venae cavae; from here, to the right ventricle. Thus the right ventricle has only one source of blood (that is, the peripheral circulation), whereas the

Fig. 168.—Patent ductus arteriosus Diagrams illustrating methods of treatment for patent ductus arteriosus. In all methods the greatest hazard is the possibility of tearing the ductus at its juncture with the aorta. The fibrosis of the ductus, together with the possibility of a subacute bacterial endarteritis, makes this a vulnerable site for tearing. The best approach is an exposure through a posterolateral incision over the fourth rib and resection of the left fourth rib or incision in the fourth intercostal space without rib resection. This gives adequate exposure and enables the surgeon to take care of any possible exigency. The ductus was first ligated by Gross with various types of suture material and then after there had been several recurrences or recanalizations, larger suture material and cellophane were wrapped around the ductus. Finally the ductus was divided and both ends sutured. This, of course, is the best way in which to be sure that recurrence or recanalization will not occur. The various methods are illustrated. *A*. The surgical approach to the ductus and important anatomical structures surrounding it. Note that the recurrent laryngeal nerve lies immediately beneath the ductus. *B*. The treatment of patent ductus as outlined by Potts using his new clamps which are straight and angulated and which will not slip or injure the vessel wall. (*1*) The ductus is divided and, (*2*) continuous mattress suture of 00000 silk is introduced. (*3*) The end is then sutured with a continuous over-and-over stitch. *C*. A method advocated by Blalock in which a purse-string suture is placed about the ductus on the aortic and on the pulmonary side (*1*). Then two mattress sutures are placed between the two purse-string sutures (*2*), and finally umbilical tape is placed around the ductus (*3*) and tied (*4*). *D*. A method advocated by Jones using the Potts aortic clamp after mobilization of the aorta and the Potts ductus clamp or any other covered hemostat on the pulmonary artery side of the ductus and dividing between the two ends, both of which are sutured. The advantage of this method is that should the ductus be torn in efforts to free it, the Potts clamp on the aorta would prevent hemorrhage from this vessel and would, at the same time, not occlude it. Complete occlusion of the aorta may produce a paraplegia within twenty-five to thirty minutes in experimental animals due to anoxemia of the spinal cord cells. *E*. The Crafoord technique consists of placing shod clamps across the aorta, one above and one below the ductus, and a third on the ductus itself as close as possible to the pulmonary artery. The ductus is divided and the aortic side is sutured. The clamps are then removed from the aorta and the pulmonary artery side is sutured. Dr. Crafoord has not reported any paraplegias with this technique. This is explained on the basis of an adequate collateral circulation.

left ventricle has two sources (that is, the blood from the right ventricle and the blood returning from the short circuit through the pulmonary artery, pulmonary veins into the left atrium, and then the left ventricle.) The left ventricle must therefore pump from two to four times as much blood as the right. The leakage of blood from the aorta which has a higher pressure to the pulmonary artery which has a lower pressure results in a fall of diastolic pressure and a slight rise in the pulmonary artery pressure. There is usually a wide pulse pressure and upon exercise the diastolic pressure may drop to zero. As in other vascular fistulae, there is a compensatory increase in the total volume of circulating blood, both plasma and cells, but in large shunts this is inadequate to meet nutritive requirements.

If this abnormal communication is not large, no serious effects are noted and such individuals remain active. Complications may result from this malformation which may be serious. These are: (1) The shunt may divert so much blood from the peripheral circulation that the physical growth is retarded and the individual stunted. (2) The leak may be so great that the useless passing of blood through it may greatly increase the work of the heart, reducing cardiac reserve even to the point of cardiac failure. (3) Endarteritis of the pulmonary artery or *Streptococcus viridans* endocarditis may be superimposed. (4) Other complications such as aneurysmal dilatation of the ductus, rupture of the ductus, and embolism from thrombosis of the ductus may occur.

The diagnosis may be difficult up to the fourth year of life. After this, the physical manifestations are typical. These are (1) "machinery murmur" which is continuous but is accentuated during systole, maximum loudness in the second or third interspace to the left of the sternum, (2) thrill in the pulmonary area, (3) stunting of growth, (4) absence of cyanosis and clubbing of fingers, (5) history of heart disease from early childhood. Fluoroscopic and x-ray examination show (1) enlarged pulsating pulmonary vessels, (2) enlarged heart, (3) enlarged pulmonary artery, (4) pulmonary congestion. The electrocardiogram is normal.

The treatment of this anomaly is its surgical interruption. Although not all authorities are agreed on the indications for surgery, most believe that it should be ligated if the patient can stand the procedure. Simple ligation may not be curative due to recanalization. Ligation with Polythene wrapped around the ductus, purse-string ligation, double ligation with injection of sclerosing agent between ligatures, and ligation with division have been used. Division of the ductus precludes recanalization and is the treatment of choice. The mediastinal pleura is incised medial to the vagus nerve. A small amount of the pericardial sac may have to be separated from the ductus. The posterior portion of the ductus must be dissected from the bronchus blindly. The line of cleavage is through the adventitia. By using special Potts clamps, even a short ductus may be divided and the ends sutured. However, this is possible only if the ductus is long enough. If ligatures are tied too loosely, tiny crevices are left due to the wrinkled and folded walls; this invites recanalization; if too tight, the ligature may cut through with re-establishment of the lumen or the development of hematoma or fatal hemorrhage. If division between ligatues or sutures is not feasible, simple ligation and in addition a purse string may prevent its reformation. Results have been gratifying.

V. *Coarctation of the Aorta.*—Coarctation of the aorta is a narrowing or obstruction to the flow of blood in the thoracic (usually) or abdominal (rarely) aorta. It is said to occur about once in every 1,500 autopsies, most often in the distal part of the arch or beginning of the descending aorta near the ductus arteriosus or the ligamentum arteriosum. If the obstruction is due to a diffuse narrowing or atresia proximal to the origin of the left subclavian, there may

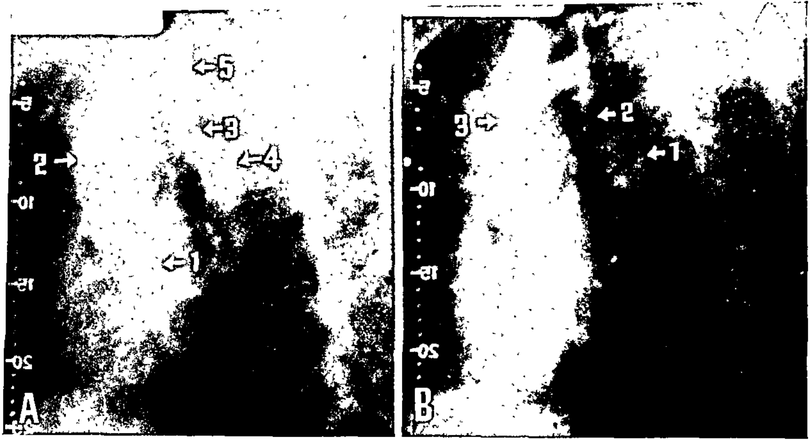

Fig. 169.—*A*. Angiocardiograms showing coarctation of the aorta. Left anterior oblique angiocardiogram at eight seconds after 70 per cent Diodrast injection showing left ventricle (*1*), ascending aorta (*2*), coarctation of aorta (*3*), poststenotic dilatation of aorta (*4*), left subclavian artery (*5*). *B*. be an insufficient supply of blood to the arm, and if the site or origin of the left common carotid is involved, there may also be a deficient blood supply to the brain. Moreover, in this high obstruction there is more apt to be associated cardiac malformation which may lead to a fatality in the first few months of life (infantile type). In the so-called adult type the stenosis is limited to a short segment beyond the origin of the left subclavian in the region of the ductus arteriosus or ligamentum arteriosum.

The complications which may ensue are (1) atheromatous changes and thrombosis, (2) rupture of the aorta due to its sclerosis and increased strain, (3) aneurysm of a localized or dissecting type proximal or distal to the narrowing, or both, (4) superimposed infection with *Streptococcus Viridans*, endarteritis, or endocarditis, (5) elevation of blood pressure in the upper part of the body due to the direct result of mechanical blocking in the main arterial pathway. As a result of this elevation of pressure in the upper part of the body there may be (a) no bad effects over long periods, (b) cardiac failure, (c) central nervous system hemorrhage. Patients usually die between the ages of 16 and 30 years. (6) Due to the prolonged ischemia of the kidneys certain changes occur in them which are thought to be related to the pressor mechanisms causing hypertension. It is a fact that even after surgical excision of the coarctation with restoration of normal continuity there may remain a persistent progressive hypertension.

The diagnosis is made by: (1) Studying the differences in pressure of the arms and legs. Normally the systolic pressure is 20 to 40 mm. of mercury higher in the legs than in the arms. In coarctation this is reversed and the pressure in the lower extremities may be unobtainable with the sphygmomanometer. There is a decreased pulse volume in the lower extremities often associated with numbness and coldness. If the presure in the arms is normal and not elevated, the narrowing may be minimal or good collateral circulation may be present. Differences of pressure in the two arms greater than 30 to 40 mm. of mercury suggest that the aorta is blocked proximal to the subclavian. In children, pressures in the arms are not greatly elevated. (2) Abnormal pulsations. These can be seen or felt (in thin persons) in the intercostals and around the axillary and scapular arteries. Collateral circulation forms in direct proportion to the degree of obstruction. (3) Systolic murmurs. These may be due to the coarctation, but murmurs are unreliable as they may be due to associated cardiac defects (bicuspid aortic valve, patent interventricular septum, patent ductus arteriosus); large tortuous collaterals may also give rise to a murmur. (4) X-ray findings. These consist of cardiac enlargement and beyond the first decade of life the following evidence: (a) Cardiac hypertrophy and dilatation are pronounced where there has been long-continued hypertension. (b) The aortic knob is usually small and lacks its normal prominence. (c) Aortic indentation may be seen. (d) There is notching or scalloping along the inferior edges of the posterolateral portions of the ribs due to erosion by pulsating tortuous intercostal arteries; this is seldom present in the upper and lower two ribs. (e) Direct demonstration by angiocardiography or aortography. (5) Ballistocardiograms show a shortened J. K. stroke. In the normal there is a full and uninterrupted downward J. K. stroke which represents the decelerated impact of ejected blood as it strikes the major peripheral resistance. The shortened stroke is due to the abrupt and early interruption of the flow.

Surgery is the only available means of combating the effects of the anomaly. The objections to the early attempts at surgery were as follows: (a) Clamping of the upper thoracic aorta in dogs was followed by spinal cord degeneration and paralysis of hindlimbs. This was due to the fact that there were not collaterals and the time consumed in anastomosis was too long (over

FIG. 170.—*A*. Plain posteroanterior teleroentgenogram showing right aortic arch causing impression on right side of barium column in esophagus (*1*), absent pulmonary artery shadow (*2*), large long aortic arch (*3*), dilatation of left ventricle (*4*), and enlarged bronchial arteries (*5*).

B. Left anterior oblique angiocardiogram at 1½ second interval. Right auricle (*1*), right ventricle (*2*), dye spilling into left ventricle through high interventricular septal defect (*3*), opacification of aorta (*4*), absent pulmonary artery (*5*).

C Left anterior oblique angiocardiogram at 2-second interval. Right-sided aorta, descending on right side of spine (*1*), right ventricle (*2*), left ventricle (*3*), bronchial arteries arising from aorta (*4*).

forty-five minutes, but it may occur in twenty minutes due to anoxemia, persistent vasospasm, or other factors as yet not determined). (b) Hemorrhage from the suture line. (c) Thrombosis. (d) Readjustment to the decreased resistance after the anastomosis. Crafoord and Nylin, Gross, Potts, Blalock, and others were the first to report successful resections and anastomoses without any untoward effects. Anticoagulants are unnecessary. Prior to this time extensive thoracic sympathectomy was done, but this resulted in only temporary improvement. Alexander was the first to ligate above and below the aneurysm and coarctation and resect them; collateral circulation was sufficient to result in a successful outcome, although the patient died later of cerebral hemorrhage. Blalock and Park suggested by-passing the coarctation by anastomosing the left subclavian with the aorta; this was tried in animals with success and has been used in man also, when the area involved in the coarctation is too long to permit resection and end-to-end anastomosis.

At present, Gross, Bill, and Peirce are using preserved arterial grafts for such cases, securing specimens from human subjects who have died in auto accidents.

Various clamps are used to hold the cut ends. The ingenious Potts clamp with its row of very fine teeth in the opposing jaws does not injure the artery and does not slip provided the clamp is applied to the vessel and not to intervening tissue. The principle is that of the Indian fakir who walks on spikes because he steps on many points at the same time. We have used small intestinal clamps shod with hollow shoestring. These do not slip and do not injure the arterial wall as proved in experimental animals. The ends of the aorta are sutured with interrupted or continuous everting mattress sutures, using No. 0000 silk swaged on No. 9 curved needle (Deknatel). Over and over suture is also successful and is easier to place. Interrupted everting sutures are less apt to be followed by lack of growth as the aorta grows.

Fig. 168*a* illustrates these abnormalities.

SYMPTOMS AND SIGNS AND TREATMENT OF PRESSURE-PRODUCING ANOMALIES

No doubt many individuals go through a normal life without symptoms from these anomalies. There may be dysphagia, stridor, dyspnea, cyanosis, hoarseness, cough, pain in the upper chest and arms. The outline includes the chief diagnostic features and complications. It is by a combination of symptoms and physical signs, together with careful fluoroscopic and x-ray examination, including barium meal studies of the esophagus, that the diagnosis can be made. Many times the true condition is not recognized until the chest has been explored. The treatment consists of ligation and division of the "offending" vessel wherever feasible. These maneuvers are shown in Fig. 166. It is important to note that the large vessels may be ligated, divided, and transplanted in children with anomalies due to the enormous collateral circulation. The carotid is the only exception and this not often in children.

Postnatal Cardiac Disease and Defects That Are Amenable to Surgery

1. Sudden Heart Failure.—Sudden heart failure during surgery may occur as a result of undue stimulation of the vagus nerves, handling of the heart, nerve shock, or causes unknown. It may be encountered

during any operation but is seen principally in (1) operations on the heart and pericardium (traction or pressure or handling of the heart may cause extrasystoles, ventricular fibrillation, and auricular *fibrillation*); (2) in any operations within the chest such as lobectomy, pneumonectomy, removal of mediastinal tumors, esophagectomy; (c) in operations of the upper abdomen or elsewhere; (d) in electrical shock.

Remedies and prophylactic measures which may be instituted may be divided into two large groups; namely, those which prevent or correct anoxemia (anoxic, anemic, stagnant, or combinations) and those which restore the heartbeat (ventricular standstill or asystole and ventricular fibrillation): (1) In surgery on the heart or pericardium, fibrillation may develop due to excessive stimulation of the vagus nerves or from handling of the heart. Beck and co-workers have recommended the use of 2 per cent procaine over the heart to desensitize it, and should fibrillation occur, 2 c.c. of a 5 per cent solution of procaine in 10 c.c. of physiological solution of sodium chloride may be injected into the right ventricular cavity. If then the heart stops, 5 to 10 c.c. of a 1 per cent solution of calcium chloride may be injected int the right ventricular cavity and may be repeated. A 0.1 per cent procaine solution of physiological saline is given intravenously as a slow drip during cardiac surgery routinely by many surgeons. (2) In pneumonectomy the hilus of the lung is injected with procaine or Metycaine before it is severed. The same is true in lobectomy. In addition, the small dissection sponges are soaked in a 1 per cent Metycaine solution. In case of ventricular fibrillation, restoration of the coordinated beat is impossible until fibrillation ceases. In all chest operations cardiac massage by manually squeezing the ventricle is useful when the heart stops. The pericardium may be opened and by gently squeezing every second, an artificial systole may be obtained. This, together with artificial respiration (by the endotracheal closed system in chest surgery), may oxygenate and circulate the blood and prevent death and injury to brain cells and heart muscle cells. (3) In any operation or circumstance where cardiac standstill occurs, Adrenalin, 1 c.c. of a 1:1,000 solution, may be injected into the right atrial chamber—the atrium rather than the ventricle because the needle puncture may set up fibrillation, and ventricular fibrillation is more difficult to control. The right atrium may be hit by going into the third or fourth interspace just to the right of the sternum. If no Adrenalin is available, a quick thump over the precordium or the insertion of the needle momentarily into the atrium may restore the beat. In abdominal operations the heart may be massaged through the diaphragm, or an abdominal incision high in the epigastrium may be made expressly for this purpose. A dilated heart or one which is greatly hypertrophied or the seat of advanced coronary disease cannot be resuscitated but any or all of the mentioned measures may be tried. The occasion for resuscitation is not common and its success is meager. We have succeeded on one occasion. The operation was our

first transthoracic esophagectomy in the human being. It was done for a carcinoma of the lower third of the esophagus. The upper third of the stomach had been removed and its proximal end closed. The posterior row of sutures had been placed, anchoring the esophagus to the anterior wall of the stomach, and the incision in the stomach had been made preparatory to completion of the anastomosis. At this time the heart stopped. Adrenalin, 1 c.c. of a 1:1,000 solution, was injected into the right ventricle and the ventricle gently massaged; 10 mg. of procaine hydrochloride was injected into the intravenous tube. Soon the heart began beating again. The operation was completed and the man made a smooth recovery. Summary: When the heart stops during an operation, the following measures should be instituted at once: (1) artificial respiration and oxygen. This prevents anoxemia and mechanically helps propel blood through the pulmonary circulation (Chapter 19). (2) Cardiac massage. With the patient in slight Trendelenburg position the heart may be massaged at the rate of 40 to 50 times per minute. This may stimulate contractions, and in addition it helps propel blood while the heart is regaining its ability to contract. This measure is easy enough in chest surgery. In other varieties the chest should be opened at once if an endotracheal tube is in place. If not, massage through the diaphragm should be started. Later, after the endotracheal tube is in, the diaphragm may be opened and cardiac massage continued. (3) Blood volume must be restored by blood and fluids. (4) Procaine hydrochloride, 50 to 60 mg. at a time in adults, should be given intravenously. (5) Two per cent procaine solution injected into the pericardial cavity about 5 c.c. at a time. (6) Five per cent procaine into the right atrium or right ventricle. (7) Adrenalin, 1 c.c. of 1:1,000 solution, injected into the intravenous tubing is useful particularly to increase arteriolar tone.

2. **Tamponade.**—If the heart action is impaired by fluid (blood or pus), *cardiac tamponade* occurs. This, of course, interferes first with the venous return. Should the intrapericardial pressure equal the systolic pressure, heart action would be impossible. As a result of the tamponade, which obviously first affects venous pressure, there is widespread edema, which first manifests itself by effusions into the pleural and peritoneal cavities. Lastly, there is general anasarca.

The chief symptoms will be a rising venous pressure with distention of the neck and arm veins, even though the arms are elevated, a falling arterial pressure with cyanosis, and faint and rapid heart sounds. In addition, the pulse is weak, often pulsus paradoxus (a pulse that is weaker during inspiration) and the skin is cold and clammy.

The causes of cardiac tamponade are penetrating wounds of the heart and great vessels, with extravasation of blood into the pericardial cavity, rupture of a myocardial infarct or aortic aneurysm, nonpenetrating wounds causing a contusion to the heart with rupture; rapidly developing effusions

or exudations or gas (pneumopericardium) in the pericardium will produce the clinical picture described. As in other instances of compression (meninges, pleura, peritoneum), the speed of its development determines the degree of symptoms. Electrocardiographic changes in the T waves and RS-T segments may occur. The *treatment* will depend upon the cause, but pressure should always be released by pericardial aspiration or by opening the pericardium (pericardiotomy). In heart injury from penetrating or perforating wounds, pericardial aspiration should be done at once and blood volume restored. If the leak is small, one or two aspirations may be sufficient, and no further surgery may be necessary. Should the pericardium fill up again rapidly, then the treatment of the primary cause is mandatory; that is, suture of the wound in the heart. Since the time element is of great importance, we usually aspirate and prepare for surgery at once, not waiting for reformation of tamponade. Pericardiotomy may be indicated in hemopericardium, suppurative and constrictive pericarditis, foreign bodies, and neoplasms. Tamponade may be absent in wounds of the heart if the pericardium is widely torn. Early shock and hemothorax are present very early.

3. **Infections and Inflammations of the Pericardium.**—As in infections elsewhere, the pericardium may be acutely inflamed, giving rise to various types of exudates, or it may be involved in a chronic cicatrizing process. The *acute* varieties have been classified according to their exudates as fibrinous, serofibrinous, serous, and purulent. The predisposing causes are pneumonia, acute rheumatic fever, empyema, wounds of the pericardium or heart, lung abscess, septicopyemias from any source. The causative organisms may be streptococci, staphylococci, pneumococci, meningococci, gonococci, *Bacillus coli,* the influenza bacillus. The disease is rarely primary, and, in addition to the pathological states mentioned, pericarditis is sometimes found in association with chronic nephritis with uremia, coronary thrombosis, and myocardial infarction, rarely with the acute exanthemas.

The symptoms and signs are those of the primary condition plus the heart effects. Often the diagnosis is missed. The symptoms and signs of infections include chills, sweats, fever, rapid pulse, malaise, anorexia, leucocytosis, and rapid wasting; in addition, substernal pain, dyspnea, dysphagia, enlarged neck veins, and all of the other symptoms of cardiac tamponade; in the dry form a friction rub may be heard, increased cardiac dullness on percussion, and, if effusion is present, distant heart sounds on auscultation, dimunition of cardiac movement on fluoroscopic or kymographic examination; x-ray studies may show obliteration of cardiophrenic angles.

Diagnosis depends on the symptoms and signs and exploratory incision (pericardiotomy) or aspiration (pericardicentesis). The latter is not without danger, for the coronary vessels, heart, or lungs may be injured. The best site for diagnostic aspiration is in the sixth inter-

space just to the left of the sternum—here the internal mammary artery is more lateral to the sternum, as is also the pleura. Open drainage is indicated in purulent pericarditis and is preferable to repeated aspiration or aspiration with injection of penicillin because of the danger of injuring the heart. This is accomplished by subperiosteal resection of the fifth and sixth left costal cartilages for about 1 to 1½ inches. The pericardium is identified and the pleura avoided; a small aspiration needle is introduced. A sample of the exudate is sent to the laboratory for culture. If the exudate is serous or serosanguineous, penicillin, 200,000 to 500,000 units, may be introduced and the wound left open. If the exudate is purulent or if purulent particles are present, the pericardium is opened and its edges sewed to the muscles or fasciae. Penicillin is instilled into the pericardial sac and is given intramuscularly in doses of 300,000 units every three hours. Sulfonamides are also given by mouth. Rarer types of infection as revealed by culture may require streptomycin, aureomycin, or Chloromycetin.

4. **Chronic Adhesive Pericardial Disease** (Adhesive Pericarditis; Adherent Pericardium; Chronic constrictive pericarditis; Pick's Disease; Pericardial Scar; Concretio Cordis; Accretio Cordis).—Scar tissue may limit the function of an organ due to a mechanical interference with its motion. This is true of dense adhesions about the lungs and intestines as well as the heart. In the latter instance the fibrous adhesions form between the epicardium and myocardium (intrapericardial), partially or completely obliterating the pericardial space (concretio cordis). Less often fibrous adhesions extend from the pericardium to the pleurae, diaphragm, chest wall, the hila of the lungs, and mediastinal tissues (extrapericardial), also interfering with function (accretio cordis or mediastinopericarditis). The *cause* of this condition is usually an antecedent acute pericarditis. Sometimes it is due to the tubercle bacillus or the pneumococcus, rarely to mediastinitis, or no recognizable cause for the calcified pericardium may be found. Rheumatic fever is probably more often the cause of mediastinopericarditis.

Pathology and Disturbed Physiology.—Normally the pericardium is attached to the posterior aspect of the sternum and the diaphragm by fascial bands and the roots of the lungs (through the pulmonary vessels). Since the lung roots are movable during respiration and the bands are loose, the heart may move and swing with respiration unimpeded. Should external adhesions occur to the lung root or other structures, movement would be curtailed or actual rotation or torsion may take place so that blood cannot adequately enter or leave the heart. Such conditions permit the heart to struggle against its "leashes," causing cardiac hypertrophy (especially if there is a complicating hypertension or valvular disease). There may be great thickening of the pericardium encasing the heart with scar tissue, or calcium may be deposited within this scar—even bone has been found here. The heart is compressed; hypertrophy cannot occur

even if there are external adhesions or valvular disease. Blood cannot enter the heart in diastole, and venous pressure rises. Since liver veins have no valves, there is an early hepatic enlargement due to passive congestion; also no valves are present in the intraabdominal veins (except azygos and spermatic or ovarian) or the intrathoracic veins, so ascites and pleural effusions occur in that order. Unlike myocardial failure, the edema in the extremities follows the above and does not precede it, although there is edema on exercising, early in the disease. Late there is generalized

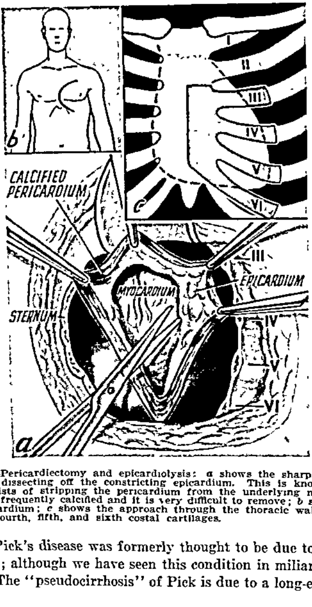

Fig. 171a.—Pericardiectomy and epicardiolysis: *a* shows the sharp dissection which is required in dissecting off the constricting epicardium. This is known as epicardiolysis and consists of stripping the pericardium from the underlying myocardium. The pericardium is frequently calcified and it is very difficult to remove; *b* shows the incision over the pericardium; *c* shows the approach through the thoracic wall with resections of the third, fourth, fifth, and sixth costal cartilages.

anasarca. Pick's disease was formerly thought to be due to a tuberculous polyserositis; although we have seen this condition in miliary tuberculosis, it is rare. The "pseudocirrhosis" of Pick is due to a long-existing passive congestion.

Symptoms and Signs.—Usually the diagnosis is not difficult. The two most common conditions which simulate the disease are cirrhosis of the liver and arteriosclerotic disease with congestive heart failure. The

symptoms which are noted first are general weakness and fatigue, dyspnea, digestive disturbances, and later swelling in the abdomen and last in the extremities. The chief signs are a "small silent" heart, liver enlargement, ascites, pleural effusion, general edema, congestion of neck veins and later all veins, pulsus paradoxus, low blood and pulse pressure, and high venous pressure. Laboratory findings include elevated venous pressure and decreased circulation time. X-ray studies show a normal-sized or small heart, often with calcareous plaques. On fluoroscopic examination there is found a decrease in the amplitude of the pulsations, especially on the right border. Electrocardiogram, according to most observers, is helpful. Broadbent's sign (a tug on the tenth and eleventh intercostals) may be present.

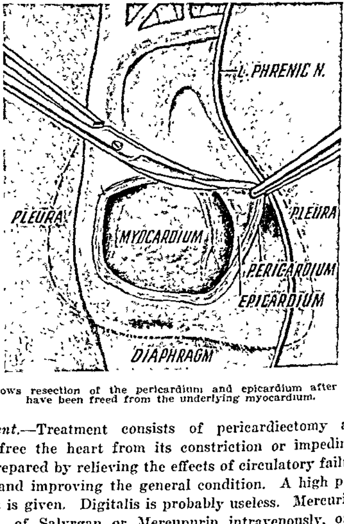

Fig. 171b.—Shows resection of the pericardium and epicardium after the structures have been freed from the underlying myocardium.

Treatment.—Treatment consists of pericardiectomy and epicardiolysis to free the heart from its constriction or impediments. The patient is prepared by relieving the effects of circulatory failure as much as possible and improving the general condition. A high protein, high vitamin diet is given. Digitalis is probably useless. Mercurial diuretics (1 to 3 c.c. of Salyrgan or Mercupurin intravenously, or Mercuhydrin or Thiomerin may be used) preoperatively and postoperatively are helpful. Transudates are withdrawn from the pleural and peritoneal cavities. A curved incision is made to the left of the sternum from the second to the sixth rib. The costal cartilages are divided

subperiostally. The internal mammary artery is ligated. The pleura is gently dissected loose from the pericardium to avoid injuring it. If densely attached, it is dissected loose after the pericardium has been removed because pneumothorax may make the operation hazardous. Incision of the pericardium is made over the left ventricle first—it has been said that freeing of the right ventricle first may cause pulmonary edema because blood would be pumped in large quantities to the lungs and the left atrium could not accept it. We have not noted this. The interventricular groove contains the descending branch of the left coronary, and particular care is exercised not to injure this. The separation of the epicardium from the myocardium is desirable and should be

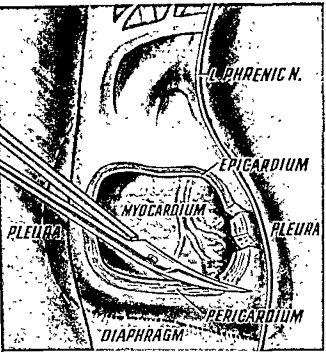

Fig. 171c.—Shows the method of multiple incisions into the margins of the remaining epicardium and pericardium (Modified from Harrington: Ann. Surg. 120: 468, 1944.)

done in addition to resection of a part of the epicardium and pericardium. In the course of the operation the pulse becomes rapid and sometimes irregular. The latter calls for temporary cessation of the operation. Moist sponges with physiological saline are applied to the heart; also procaine as previously described (see auricular fibrillation). The upper part of the wound is closed carefully, including the intercostal muscles to the sternum. The fifth and sixth cartilages are removed and this area is closed only by subcutaneous tissue and skin. Two Penrose drains are inserted in the lower angle to take care of serous exudate. They are removed in thirty-six to forty-eight hours. Oxygen is used postoperatively. The mortality of this operation is about 35 per cent.

5. **Cardiac Trauma.**—The heart may be injured with or without penetration as is the case in abdominal injuries (Chapter 20). Contusions and compressions of the chest are not uncommon in automobile accidents where the driver is thrown against the steering wheel. The heart may be slowed greatly by vagus nerve stimulation after chest contusions, its myocardium may be injured and inactivated by ecchymosis, or the heart may rupture. Doubtless the last effect is more often seen in old arteriosclerotic hearts. The effects of extreme slowing may resemble the carotid sinus syndrome and with various degrees of syncope. A contused myocardium will give all the symptoms and signs of cardiac insufficiency and should be treated as such. Rupture of the heart will show the signs of tamponade and will require cardiorrhaphy. Aspiration should be done first to see whether the rent is of sufficient size to require open operation.

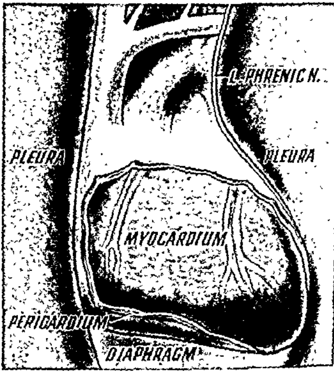

Fig. 171*d*.—The complete operation. Recent studies by Holman and Willett tend to prove that failures following pericardiectomy are due to incomplete decortication. This is chiefly due to adhesions about the superior and inferior vena cava. These authors believe that the exposure necessary for this type of decortication requires a median sternotomy with transverse division of the sternum in the second interspace. The diagnosis of constrictive pericarditis is based upon so-called Beck's triad which consists of the following symptoms: (1) a small, quiet heart; (2) ascites; and (3) increased venous pressure. The best proof that a complete operation has been done, which includes the liberation of all borders of the heart and both venae cavae and also the inferior cardiac border of the pericardium lying between the heart and the diaphragm, is a prompt and permanent lowering of the venous pressure.

Penetrating wounds of the heart are seen often in war but are by no means rare in civilian practice. The penetration may be very small when produced by small sharp instruments (ice pick). Sometimes foreign bodies will penetrate the pericardium and not enter the heart. More

often the wound is large enough to produce a hemopericardium with all of the symptoms and signs of acute tamponade as previously described. Thus a penetrating wound may produce very few symptoms or it may mimic various types of heart disease when foreign bodies are present, or it may cause serious interference with heart action due to tamponade. The diagnosis is not difficult with the aid of the x-ray and fluoroscope. In all cases of cardiac tamponade, progressive hemothorax, or persistent shock in chest injuries the possibility of a cardiac wound must be considered. The diagnostic signs as previously mentioned include a period of no symptoms following chest injury and then rapid collapse and shock, faint heart sounds and weak pulse, elevated venous pressure (normal being 6 to 12 cm. of water) as elicited quickly by holding the hands up and noting the persistence of distended veins, and, lastly, a low arterial pressure. These symptoms develop quickly because the pericardium is obliterated rapidly after the pericardium is distended.

Fig. 172.—This patient was a male, aged 45 years. He was stabbed with a large knife just to the left of the sternum in the third interspace. On admission the patient was pulseless, cold, and clammy. The blood pressure could not be obtained. The veins of the neck stood out prominently. The patient was gasping and was semi-conscious. A diagnosis of cardiac tamponade due to stab wound of the heart was made and the patient was explored through the third interspace. The third and fourth costal cartilages were divided and the ribs spread apart. The left pleural cavity was filled with blood due to the bleeding from the internal mammary artery which had been severed. This was doubly tied. The pericardium was opened and an enormous quantity of blood escaped. At this time the patient's blood pressure began to rise. Blood was aspirated from the pericardial sac but was collected in a sterile container and returned very rapidly in the antecubital vein and both anterior tibial veins. The rent in the right atrium was easily identified and was closed with interrupted sutures of silk. The pericardium was closed except for a very small opening which was left to permit egress of any accumulation of serum or blood in the pericardial sac. The pleura and intercostal muscles were closed with interrupted silk sutures. A catheter was placed in the suture line and suction was applied and the lung was inflated. The catheter was then withdrawn quickly and the sutures tied tightly. The costal cartilages were approximated with silk ligatures and the skin closed with interrupted silk sutures. *A*, Postoperative photograph showing the T incision which was made to gain adequate exposure. *B*, X-ray photograph of the patient on the fifth postoperative day. He made an uneventful recovery.

Pathology.—In general then there are three chief types of injury producing different clinical pictures and requiring different kinds of management: (1) The small perforating wound produces a small hole in the pericardium and in the heart. Bleeding is prodigious at first, but soon the hole is sealed due to the early clotting which in turn is caused by defibrination of escaped blood as a result of the cardiac action. For the same reason the hole in the parietal pericardium seals, causing early cardiac tamponade with its chain of symptoms and signs. (2) The large lacerated wound does not seal off in the heart or pericardium so that there is cardiac tamponade and signs of hemorrhage into the pleural cavity since blood cannot escape from the pericardium as rapidly as it is lost from the heart. (3) Incised wounds produce bleeding from the heart, and the pericardium is open so that the symptoms and signs are chiefly those of hemorrhage into the pleural cavity and to the outside. The defibrinated blood in all varieties remains liquid.

Usually the right ventricle is injured because of its vulnerable position; next, the left ventricle; then, the right atrium. Often there is associated injury to the pleura, lung, internal mammary artery, and, of course, the pericardium. Sometimes there are two or more holes present.

Treatment.—The treatment may be outlined as follows: Preoperative management consists of the administration of plasma and whole blood to restore blood pressure and encourage reaction from shock. Some authors advise against this because of the possibility of increasing the tamponade. Usually this is not true because blood is being lost rapidly through the pericardial rent, and, moreover, if the transfusion is not given under pressure, it will flow into the vein slowly due to the increased venous pressure. Most important is the fact that blood will be running into the cannulated vein in the ankle and arm when the pericardium is opened, and a large quantiy of blood is lost in a short time. Aspiration should be done first because it relieves tamponade, and in small rents caused by picks, pins, or small knives it may be curative (type 1). However, this should be done in the operating room while preparations are being made for immediate surgery (types 2 and 3). In a recent case of a large rent of the right atrium produced by a screw driver, over 2,500 c.c. of blood were lost and replaced in thirty-five minutes with complete and uneventful recovery after cardiorrhaphy. The anesthetic of choice is either administered by the endotracheal tube. Local anesthesia is undesirable and a waste of time—gas anesthetic agents may not be effective due to the severe anemia—ether is best. A T incision or a curved incision may be used. The second, third, and fourth costal cartilages are divided and the ribs spread, the internal mammary artery doubly ligated and divided, and the pleura entered through the third interspace. The lung is packed away and the pericardium opened. If the rent is immediately seen, the finger is held over it and it is sutured with silk. If manipulation is required,

5 c.c. of a 1 per cent procaine solution is injected into the right ventricular cavity to prevent severe bradycardia, asystole, or auricular fibrillation. Traction sutures in the ventricular apex are not usually employed. The pericardium is loosely closed so that serum may exude into the pleural cavity. The lung is inspected, then inflated, and the chest closed without drainage or with closed drainage if lung injury was present. Postoperative care consists of treatment for shock and its prevention by blood transfusion; anoxemia is treated by oxygen inhalation; penicillin and sulfadiazine are used to prevent infection. The patient is kept at rest for about three weeks.

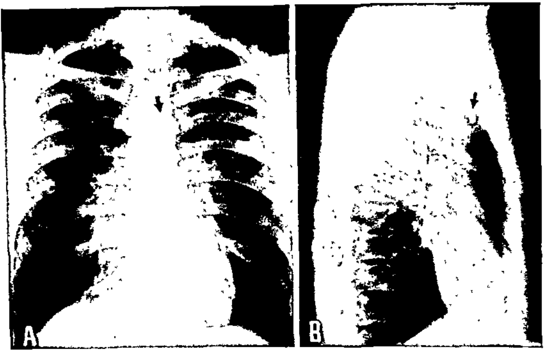

Fig. 173.—X-ray photograph showing a foreign body within the pericardial sac. This patient was a man 32 years of age, who complained of angina pectoris which had been diagnosed elsewhere. The pain was typical in its radiation and was not constant but came after the slightest exertion or excitement. The patient stated that when he was 12 years of age he was accidently shot in the chest and that the bullet had never been recovered *A*. Posteroanterior x-ray photograph showing the bullet to be directly over the ascending arch of the aorta and lying between the first and second ribs anteriorly. *B*. X-ray photograph in a left lateral view.

Operation was done through an incision which required the removal of the upper portion of the sternum and a portion of the first and second ribs. The bullet was found within the pericardial sac directly in the groove between the aorta and the pulmonary artery Following removal of this bullet the anginoid attacks disappeared and the patient has remained well. This is an illustration of some of the vagaries of the symptoms produced by foreign bodies within the pericardial sac. During World War II foreign bodies were found in all portions of the pericardial sac and the heart muscle as well, and some within the heart chamber. These were successfully removed in large numbers. This illustrates the problem as it appears in civilian practice. (Case referred by Dr. John MacDonald.)

Foreign bodies should be removed if severe symptoms occur (precordial pain, dyspnea, asthenia, and cardiac neurosis) or if there is evidence of pericardial or myocardial change or danger of a future complication such as dense fibrosis, infection, erosions of the myocardium

or vessel wall, embolism, and bacterial endocarditis. Since any of these complications may result, it is our policy to remove foreign bodies, except extremely small ones, early.

6. **Cardiac Ischemia.**—We have seen that the heart is permitted free motion by its anchorage to the body through the great vessels. This arrangement does not provide for continuity of tissue and therefore the development of new or compensatory vasculature does not occur readily. The superior, middle, and inferior cardiac nerves carry efferent fibers and are derived from the superior, middle, and inferior cervical sympathetic ganglia, respectively. In addition, there are some nerve fibers coming from the sympathetic ganglia of the second to the fifth thoracic vertebrae inclusive. These carry afferent and efferent fibers.

Ischemia of the heart muscle may be due to functional spasm of the coronary arteries or their occlusion. If it is the former, as may occur in angina pectoris, sympathetic ganglionectomy may help. If the latter, some method of forming collaterals is indicated.

Sympathectomy is done through a left paravertebral incision from the second to the sixth rib. Sometimes both sides must be interrupted; usually the left side is sufficient. Ribs are severed and spread apart. The pleura is pushed aside and the second to fifth dorsal ganglia and rami communicantes removed. The operation has some advocates and results are usually temporary.

If the coronary is occluded, collaterals must be established. Beck and colleagues have pointed out that the right coronary artery, the descending ramus of the left coronary artery, and the circumflex ramus of the left coronary artery possess capillary beds that do not anastomose with each other. Intercoronary communications may occur after occlusion provided death of the myocardium from infarction does not occur or ventricular fibrillation with heart failure does not ensue. The patient would perish from either. Since both are due to anoxemia, any method of delivering oxygenated blood would tide the patient over this critical period and then collaterals would form. Anastomoses also occur from inflammation—in fact, ligation of the coronaries may be done with survival of the experimental animal if abrasion of the heart had previously been carried out. A third method of stimulating collaterals advocated by Fauteux follows the idea used in peripheral vascular disease of stimulating collaterals by venous ligation—in the heart the vena magna cordis may be ligated in occlusion of the left ramus descendens of the left coronary. Beck has sutured parietal pericardium, mediastinal or omental fat, and skeletal muscle to aid in relieving myocardial ischemia. His results have been encouraging. The use of calcium and magnesium silicate in powder form used sparingly to produce irritation and collateral blood supply also has given promising results. Other substances used are talc, asbestos, and acriflavine. Admittedly these procedures are still in the experimental stage.

Other potential sources of new blood supply which have been utilized are the thoracic wall, including the pectoral muscles, the internal mammary and intercostal arteries, the pericardium and its fat, and the lung (cardiopneumonopexy—Carter).

Beck has recently succeeded in anastomosing the aorta to the coronary sinus using a transplanted vessel. He first ligates the coronary sinus so that it will enlarge and hypertrophy; then at a second stage the transplant (jugular vein, bronchial artery) is implanted. He has recently reported a successful case in a man using a portion of the bronchial artery as a graft.

Fauteux has attempted to relieve anginal pain by pericoronary neurectomy combined with ligation of the coronary sinus to increase the amount of blood available to the myocardium.

Aneurysm of the heart following severe contusion or following infarction may someday be treated by excision and suture as demonstrated by Murray, who successfully resected acutely infarcted areas in dog hearts.

7. **Valvular Disease.**—Stenotic valves have been dilated and incised, excrescences have been removed from valves in subacute bacterial endocarditis, and the human heart has been cannulated through the antecubital vein in the arm to help in diagnosis and treatment of cardiac disease. The results of intracardiac surgery are equivocal and the procedures are as yet experimental. Recently a new method has been advocated in the treatment of mitral stenosis so that the heart itself will not have to be attacked. This is proposed by Bland and Sweet. The operation consists of providing a venous shunt in advanced mitral stenosis so that blood is directed from the pulmonary vein into the azygos vein in order that the high pressure within the former will be decreased by shunting blood into the systemic venous system. The object of this operation is, of course, not to cure the mitral stenosis but to prevent the recurrent attacks of pulmonary edema which may be fatal and which are often encountered in advanced mitral stenotic disease. Other procedures designed to relieve the so-called "cardiac lung" due to left ventricular failure or mitral stenosis are ligation of the inferior vena cava below the renal veins to decrease the amount of blood reaching the right atrium and tricuspid valvulotomy which is also designed to delimit the volume of blood reaching the lungs.

Valvulotomy has been successfully performed by Bailey and others in mitral stenosis. The operation is performed without dislocating the heart from a position of optimum function. A small opening is made in the left auricular appendage or the left superior pulmonary vein and the cardiovalvulotome introduced. By this approach from the auricular side the funnel directs the cutting instrument toward the leaflet margin. A "selective insufficiency" is created and "valvuloplasty" by resection of the immobilizing commissure bridges. In this way mitral insufficiency is

not substituted for mitral stenosis. Undue acceleration of the heart increases pulmonary vascular pressure and is associated with attacks of pulmonary edema, and therefore tachycardia must be prevented if possible. Patients with mitral stenosis who have an adequate cardiac output but severe pulmonary symptoms either have a combined stenosis (insufficiency with the latter predominating) or the pressure in the left atrium may be extremely high so that an adequate flow may be maintained through the stenotic valve. In such cases perhaps the creation of an interatrial septal defect may relieve the pulmonary hypertension.

Rheumatic mitral stenosis is one of the most common causes for peripheral arterial embolism. The site of the thrombus from which the emboli originate is the left auricle or its appendix in most cases. Therefore, Madden has recently resected the left auricular appendix in patients with rheumatic heart disease and mitral stenosis with or without auricular fibrillation who have had peripheral arterial embolism.

Experimental Studies

Björck and Crafoord have shown that if oxygen is supplied to the brain, the rest of the body can do without it for twenty minutes or more without damage. Björck has described a cardiopulmonary machine which takes blood from the veins and lets it flow through a horizontal cylinder, the upper half of which is filled with a stream of warm oxygen flowing in the opposite direction. Discs rotating within the cylinder dip into the blood so that new films of blood are continually formed on their surfaces and oxygenated. The blood is returned by two pumps (working in parallel alternate pulsations) which are regulated by a photoelectric cell actuated by the blood level in the cylinders.

In order for the blood to flow without clotting, all surfaces are coated with silicones to make them smooth. To prevent embolism, the blood is passed through a fine-mesh filter, and to avoid hemolysis, oxygen is used and sodium bicarbonate solution is added to the blood. Lastly, to prevent hypoglycemia, glucose is added. The experiments have been done on dogs. The machine is filled with blood from a donor and this is pumped through the dog's external jugular vein into the superior vena cava and withdrawn from the common carotid, after traversing the lungs which have been automatically inflated by an automatic respiration machine. In this way the dog's brain is perfused with its own blood mixed with donor blood that has gone through its lungs. Experiments have shown that after the vertebral arteries and veins have been divided, the brain could be perfused through the right common carotid artery while the left one was clamped, venous blood being withdrawn from the superior vena cava by a cannula inserted through the external jugular vein. Dogs perfused in this way survived for ninety-three minutes and remained normal. Dogs survived thirty-three minutes with a superior and inferior venae cavae both occluded and azygos vein ligated. With this machine it is hoped that intracardiac operations can be performed by temporarily using an artificial heart as described.

Templeton and Gibbon have attempted intracardiac operations by doing their work in stages. First they found that dogs can tolerate clamping of both venae cavae for nine minutes without neurological damage. Their operations on dogs were done in stages as follows: Circulation through the heart was stopped for three minutes, resumed for the next forty-five, and stopped again for six minutes. The right auricle was incised and the right cusp and papillary muscle of the tricuspid valve resected. Then T-shaped vein grafts were fashioned from the azygos (to form a leaflet) carrying with them a stump of the supreme intercostal vein (to form the chorda tendinea). This

was turned inside out and the ends closed. Pericardium grafts were also trimmed to a T shape. Circulation was then interrupted long enough to permit a suturing of the graft in place.

Jongbloed has succeeded in constructing a mechanical heart-lung system which maintains the whole circulation to brain, spine, thoracic and abdominal viscera. Blood is pumped out from the superior and inferior vena cavae by way of the external jugular and femoral veins respectively; it is then oxygenated and pumped in (left heart of the apparatus) to both femorals, using a T tube, so that blood flows distally, and since the aorta is empty it flows proximally to the aortic valves which remain closed because there is no blood in the left ventricle and the artificial pressure in the aorta is higher than the pressure in the right ventricle. From the aorta blood flows normally to all aortic branches, including the coronaries. Animals have been kept alive for two hours with recovery with this apparatus.

8. **Cardiac Neoplasms.**—Cardiac neoplasms are extremely rare. In the pericardium, primary neoplasms, include fibroma, lipoma, angioma, and sarcoma. secondary tumors from the myocardium and mediastinum and bronchogenic carcinoma of the lung occur by primary extension or in the pericardial blood vessels. Echinococcus cysts have been reported in the pericardium.

Endocardial tumors that have been reported are as follows: vascular hamartoma, myxoma, fibromyxoma.

Myocardial growths are also very rare. Benign growths are as follows: fibroma, angioma, lipoma, leiomyoma, and myxoma. Rhabdomyoma is seen in connection with tuberous sclerosis (see Chapters 6 and 18). Sarcoma, primary and secondary, are reported. Melanoma may metastasize to the heart. Carcinoma from mediastinal structures (esophagus, lungs, thymus, lymph nodes), leucemia, and lymphosarcoma may involve the myocardium. Echinococcus cysts may be found in the heart.

Diagnosis is not so difficult now because of the help of angiocardiography, but the tumor is usually called a mediastinal tumor of lymph node origin. As exploratory thoracotomy becomes a more common operation many of these growths will be found. At least those of the pericardium may be amenable to surgery, and perhaps some of the epicardial and myocardial growths as well.

9. **Pulmonary Embolism.**—A discussion of the probable causes of this complication following surgery or bed rest will be *found in* Chapter 5 and also in this chapter under Veins. This ominous event strikes suddenly in young persons and old and often without warning. Some authors say that 16 per cent of postoperative deaths are due to pulmonary embolism. In 1936 we made a study of postoperative deaths in the Indiana University Medical Center for a period of five years. There were 5,133 so-called major operations with 155 deaths, a general mortality rate of 3 per cent. Of this group, 53, or about one-third of the deaths, were due to what we termed circulatory causes, an incidence of 1 per cent. These we divided into cardiac, arterial, venous, and hemorrhagic shock. Of the 53 deaths due to "circulatory" causes, 18 were due to pulmonary embolism. In 1940 we repeated our studies. There were

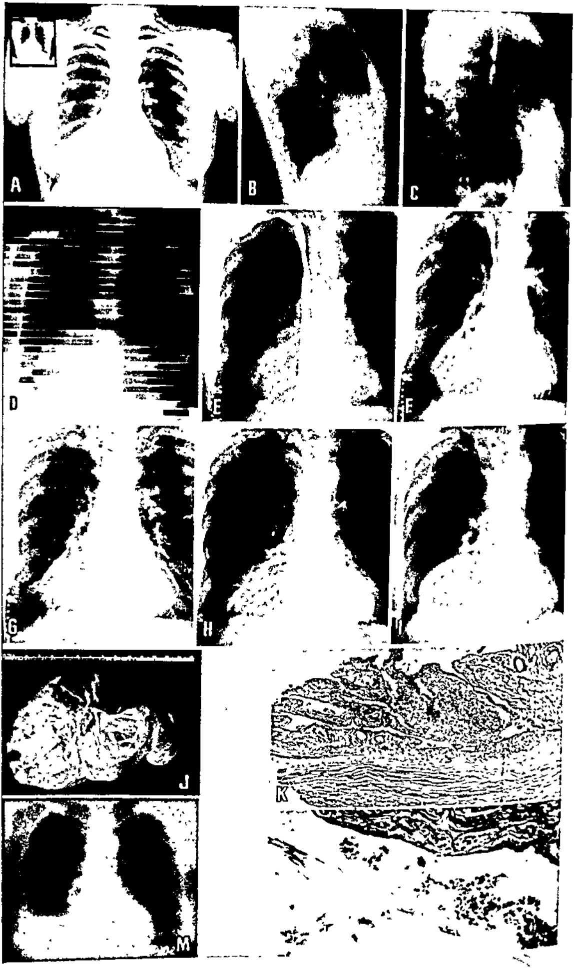

Fig. 174.—*See opposite page for legend.*

8,979 major operations with 162 deaths, a general mortality rate of 1.8 per cent. Of this group, 68, 42 per cent, of the deaths were due to circulatory causes, an incidence of 0.75 per cent. Of the 68, only 10 were due to pulmonary embolism.

The sudden collapse, pallor, cyanosis, dyspnea, and thready pulse, together with a sensation of a constriction about the chest, sometimes a cough or vomiting, and a fear of impending death, is the usual picture—not unlike coronary thrombosis. If there is a complete obstruction of the pulmonary artery, death will ensue at once. If the obstruction is incomplete, death may occur later due to diminished circulating blood volume and shock or to right-sided heart failure. (See Chapter 14.)

Death may occur in a few minutes; therefore, surgery must be prompt if embolectomy is to save life. Since the main pulmonary artery with a saddle embolus may be the cause, intrapericardial approach may be necessary. Trendelenburg described the operation. In 100 cases reviewed by Elkin, 15 are living. Since this per cent of survival is not much greater than that without surgery, the value of embolectomy is open to question. If the diagnosis can be made with certainty and surgery done immediately, the operation is indicated, followed by the use of heparin. Since this is ordinarily not feasible, more stress should be placed on the methods of prevention of pulmonary embolism, and its repetition in sublethal emboli, than on their cure. One last question still unanswered deserves consideration. Frequently an embolus in one pulmonary artery is lethal—why, then, is not pneumonectomy always fatal? Many hypotheses are given. A few of the more important ones are (1) the lung becomes acclimated to decreased blood supply in the interval

---

Fig. 174.—Pericardial cyst (lymphogenous). Series of x-ray photographs and angiocardiograms which were necessary to work out the true nature of a mediastinal tumor and the removed specimen, microscopic picture of the specimen, and the postoperative x-ray photographs showing the lesion removed. (Lymphogenous cyst of the pericardium—cystic hygroma.) This woman, G. S., aged 57 years, had a routine chest film made by the State Board of Health Service and she was told that an abnormality existed and was referred to the family physician. The small x-ray photograph (inset in *A*) shows the routine 35 mm. film. X-ray photographs *A* and *B* show posteroanterior and lateral films of the chest. Following this procedure, we could not decide whether the lesion was a mediastinal tumor, an aneurysm of the right bentricle, a cyst of the pericardium, or a tumor of the ventricular wall. *C* is an x-ray photograph, lateral projection, showing a barium swallow which was made to rule out possible esophageal tumor. *D* is a roentgenkymogram which shows the tumor on the right side but does not aid materially in making a diagnosis between intracardiac or mediastinal tumor or pericardial tumor. Fluoroscopic examination was not helpful because of the transmitted pulsation. Angiocardiography revealed the diagnosis accurately. *E*. The first film taken shows the dye flowing into the right atrium. The small ball on the left shows the time in seconds. *F*. The dye is leaving the right ventricle and going into the pulmonary artery and its branches which are clearly seen in both lungs. *G*. The dye is now seen to be coming back through the pulmonary veins into the left atrium and the left ventricle. *H*. The dye is now seen in the left ventricle and is beginning to come out through the aorta. *I*. The aorta is now plainly visualized. It is to be noted that after the influx of dye into the right atrium and right ventricle, the diagnosis was clearly made because the tumor mass is seen to be outside of the heart. Since it was attached to the pericardium as noted by pulsation and since it was partially transluscent, it was diagnosed as a pericardial cyst *J* is a photograph of the removed specimen. *K* is a low-power photomicrograph establishing the diagnosis of a pericardial lymphatic cyst. The section shows some lymph spaces and small cystic spaces. *L* is a high-power photomicrograph. Note the endothelial lining, the lymphocytes, and smaller cystlike spaces which are probably dilated lymph vessels. The larger space is a large lymph vessel. *M* is the postoperative film taken in the posteroanterior position approximately ten days following extirpation of the cyst A very small amount of serum is present in the costophrenic angle. This was absorbed. The patient made an uneventful recovery and has remained well to date. (Case referred by Dr. Russell Henry.)

between thoracotomy and ligation; (2) arteries and veins are tied; (3) a wider area of artery is involved and the arterial spasm in both sides will be greater after embolism than ligation; (4) ligation under anesthesia and local *anesthesia at the hilus prevents auricular fibrillation.* (5) Small embolic particles lodge in the arterioles and capillaries of the lung in showers or in the arterioles alone. (6) A large embolus which is saddle in nature and occludes both main branches of the pulmonary artery.

10. **Mediastinal Emphysema.**—Mediastinal emphysema should be mentioned here because of its effect upon the heart. It is evident that if mediastinal pressure exceeds venous pressure, blood will not be returned by the veins to the right atrium and death from anoxemia will occur. The causes for mediastinal emphysema may be serious or trivial. In the latter group may be mentioned straining, lifting, or coughing. We recently saw a boy with this condition after jumping across a gate. He missed the gate post but did not strike it with his chest so far as we could tell. Lacerations of the lung or bronchi, chest contusions, concussion blast (see Chapter 14—Shock), excessive positive pressures in mechanical resuscitators, especially in infants, may produce it.

Tension pneumothorax may cause the condition by direct penetration of the mediastinal pleura or by extension along the root of the lung. Conversely, a ruptured lung or bronchus may allow air to enter the mediastinum under the visceral pleura along the lung root without pneumothorax. Soon the air escapes into the subcutaneous tissues of the neck, face, and even the entire body (subcutaneous emphysema).

In the latter instance mediastinal pressure is decreased. Sometimes air enters the pericardium along the pericardial covering of the large vessels, causing pneumopericardium.

The symptoms and signs are typical. There is subcutaneous emphysema of the neck and face, the jugulars stand out, and there is dyspnea and cyanosis. X-ray shows a widened mediastinum and may show air in lateral films. If no subcutaneous emphysema is evident, the picture resembles cardiac tamponade.

Treatment depends upon the cause, but first and foremost is release of air from the mediastinum if possible. A large, No. 18 gauge needle is introduced into the jugulum; usually the relief is dramatic and an audible hissing sound may be heart. Tension pneumothorax must be corrected immediately (see Chapter 19). If the mediastinum fills up again, incision in the jugulum is indicated although mediastinitis is to be feared. If the air cannot be reached by an incision in the jugulum and if pressure symptoms continue, an incision is made over the heart, avoiding the pleura. Even the pericardium may be opened if found necessary.

If the mediastinal emphysema is mild, it should need no active treatment and will be absorbed after the primary cause is corrected. Mild cases without apparent cause need no treatment.

BLOOD VESSELS

Harvey first described the circulation of the blood. He knew that the arteries carried blood from the heart and the veins carried it back, but he could not explain how it got across from arteries to veins. We now know it is by way of the capillaries. These tiny vessels, whose walls are made of a single layer of endothelial cells, carry food and oxygen into the tissue and remove waste products from them. The liver and kidney, interposed in the circulatory system to detoxify and remove waste products from the blood, have two sets of capillaries for blood to pass through before returning to the heart. The lymph vessels are important in carrying paticulate matter away. The arteries (except the pulmonary) carry oxygenated blood, and the veins (except the pulmonary vein) carry oxygen poor blood. (See Chapter 11.)

The large arteries have been termed arteries of storage, while the smaller arterioles, arteries of distribution. These terms are accurate because at any one time about 7 per cent of the blood is in the capillaries and 93 per cent in the large arteries, their main and terminal branches. Some vessels are tortuous, as in the cheeks, tongue, and lips, which are movable, or the uterus, which is expansible. In the liver, spleen, bone marrow, and adenals wide tortuous vessels exist called sinusoids. The distinctive features of the blood vessels in the portal, splenic, renal, and cardiac circulations are discussed under their respective regions. Peculiarities of the pulmonary circulation are reviewed in the chapter dealing with the respiratory system. The flow of blood to all organs can remain suspended for as long as twenty to thirty minutes without any subsequent signs of organic damage provided an adequate supply to the brain is secured. In the experimental animal this has been accomplished by creating an anastomosis between carotid and jugulars on one side to those of another dog of the same size.

Veins have thin walls (which are easily compressible) and valves within the lumen placed usually just distal to the mouth of an entering tributary. They are semilunar, usually in pairs, and their free borders are turned toward the heart. They are composed of endothelium with some fibrous tissue, and the wall of the vein is dilated on the proximal side of each valve into a pouch or sinus. Valves are more numerous in the deep than superficial veins and more numerous in children than in adults. These valves direct the flow toward the heart and are present in all veins except those of the abdomen (the azygos has imperfect valves and valves are present in the testicular veins), the thorax, the brain, and some veins of the face (for example, the angular). Tributaries to the valveless veins in the thorax and abdomen have efficient valves. This arrangement prevents overdistention of the cerebral veins and sinuses in vomiting or coughing and of the veins of the extremities in increased intra-abdominal pressure from ascities or new growth.

Edema of the extremities as a result of increased intra abdominal pressure occurs only if the valves are imperfect. In the experimental animal this mechanism is easily demonstrated. The artery to an extremity is left intact. The vein is divided and its proximal side is ligated. Into the distal segment a cannula is inserted, which is attached by rubber tubing to a manometer. The venous pressure soon equals the arterial pressure. If now the extremity is squeezed, the venous pressure may go much higher than the arterial, due to the valves, which act like a hydrostatic pump. If the pressure in the abdomin increases, so will the pressure in the veins—until systolic pressure is reached; then circulation ceases and the viscera become blanched.

Roughly, the pressure in the vascular tree is highest in the aorta and then decreases until its lowest point is at the right auricle. Venous blood flow depends on the following factors: (1) The contraction of the left ventricle (vis a tergo) supplies the force which keeps the blood stream moving. (2) The subatmospheric pressure within the thorax (−6 mm. of mercury in inspiration to −2.5 mm. of mercury during expiration) expands the veins and literally sucks blood into the thorax. The venous pressure at the

right auricle is +5 mm. of water; therefore, blood enters the thorax easily. (3) The action of the right side of the heart, by quickly emptying the auricle and ventricle, allows blood to flow in unimpeded. (4) The massaging effect of muscles forces blood along the veins. This is most notable in the legs. (5) The effect of gravity in impeding the venous flow is especially important in the veins of the thorax and abdomen (which are valveless) and in varicose veins (in which the valves are functionless).

In vomiting, the diaphragm descends and the abdominal muscles contract. Intra thoracic pressure is increased as is evidenced by the distention of the veins of the neck, although part of this may be due to the head-down position assumed in vomiting. Abdominal pressure is greatly increased and is much more than the intrathoracic pressure. This sends blood up into the thorax. By reflex vagus inhibition the heart stops momentarily and then the next beat is more forceful When the vomiting has ceased, the diaphragm ascends, the abdominal muscles relax, and the blood flows back into the abdomen (no valves). Were it not for such a mechanism there would be an overdistention of the right heart and death from asphyxia. Anoxemia plus stasis causes death of tissue. This is as true of varicose ulcer as of the patient as a whole. In the Trendelenburg position blood flows into the thorax. If there is anoxemia, the heart beat is increased (cardioaccelerators—Bainbridge reflex), but the right ventricle cannot force blood into the inactive lungs, stasis occurs with right-sided cardiac inadequacy, there results a fall in arterial pressure, and death may occur.

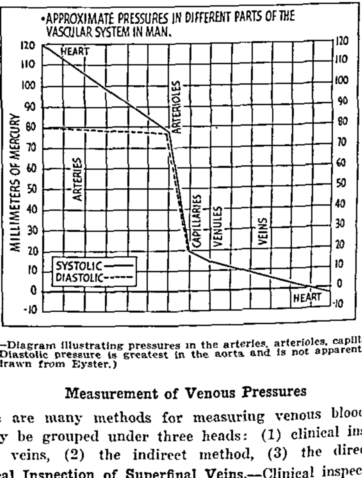

Fig. 175.—Diagram illustrating pressures in the arteries, arterioles, capillaries, venules, and veins. Diastolic pressure is greatest in the aorta and is not apparent in the capillaries. (Redrawn from Eyster.)

Measurement of Venous Pressures

There are many methods for measuring venous blood pressure. These may be grouped under three heads: (1) clinical inspection of superfinal veins, (2) the indirect method, (3) the direct method.

Clinical Inspection of Superfinal Veins.—Clinical inspection is the most widely used method. A few illustrations may be given to illustrate the method.

Jugular Veins.—With the patient in a semisitting position these veins are normally not filled above the plane of the manubrium. Distention of the veins above this level indicates a high venous pressure in the superior vena cava system. If, in addition, there is hepatomegaly with or without leg edema, there may be a general increase in venous pressure as seen in cardiac failure. At times in heart failure the jugulars are not greatly distended unless pressure is put on the abdomen (hepato-jugular reflex).

Veins of the Hand.—With the patient sitting, the arm is slowly raised. The distance of the point at which collapse is observed from the plane of the right atrium (taken as the fourth intercostal space) is a rough measurement of the venous pressure. Normally it is 100 mm. of water. In cardiac tamponade the veins do not collapse even when elevated to 90 degrees.

Veins of the Undersurface of the Tongue.—Veins of undersurface of tongue are inspected while the patient is sitting. These veins are normally collapsed; when distended, the venous pressure is equivalent to 200 mm. of water or more.

Veins of the Leg.—The veins of the leg are observed with the patient in a semireclining position and are useful in tests of peripheral vascular disease and intra-abdominal increase in pressure.

Indirect Method of Determining Venous Pressure.—Indirect method of determining venous pressure as employed by Eyster depends on the principle that the least pressure necessary to cause collapse of a vein is approximately equal to the pressure within its lumen. Various devices have been perfected to determine pressure in this way.

Direct Method of Determining Venous Pressure.—Direct method of determining venous pressure is the usual method employed today. It is done by inserting a needle in the vein (about 19 or 20 gauge). To this needle is attached a three-way stopcock. To one arm a 5 c.c. syringe is attached and to the lateral arm a small rubber tube is fixed to which a glass manometer is attached. The syringe contains physiological saline. First the manometer is filled and then the stopcock is turned and the rest of the saline is injected into the vein. Then the stopcock is turned again, permitting saline to flow into the vein until it reaches its pressure level. The same device without the syringe attachment or three-way stopcock is used in reading splenic vein, portal vein, and pulmonary artery pressures.

Normally the venous pressure varies with the position of the patient, habitus, distance of the manometer from the skin, etc. In the arms it is usually between 50 to 150 mm. of physiological saline solution. The pressure in the femoral vein is a little higher than in the antecubital vein in the same person. In obese people it may be 40 to 50 mm. of saline higher.

TABLE XIV

DIAGNOSTIC VALUE OF REGIONAL DIFFERENCES IN VENOUS PRESSURES
(From Hussey and Jeghers: New England J. Med., 1947.)

PRESSURE DATA	DIAGNOSIS
Diminished in all peripheral veins	Peripheral vascular collapse (shock); syncope
Elevated in all peripheral veins	Right-sided and generalized cardiac failure; constrictive pericarditis (Pick's disease); pericardial effusion; uniform loss of negative chest pressure (obstructive emphysema); Bernheim syndrome; varicose veins
Normal arm and elevated in leg veins*	Ascites; tympanites; pneumoperitoneum; pregnancy; hypernephroma and other tumors of kidney, with invasion of inferior vena cava; primary carcinoma of liver, with invasion of inferior vena cava; primary tumor of inferior vena cava; thrombosis of inferior vena cava; ligation of inferior vena cava; masses in peritoneal cavity; solitary abscess in right lobe of liver; subphrenic abscess on right; echinococcus cyst of liver; large tumor mass in right lobe of liver
Elevated in arm and normal in leg veins	Aneurysm of aorta; ?dilatation of aorta; lymphoma of mediastinum; metastatic masses in mediastinum; primary tumor of mediastinal structures; abscess of mediastinum; thrombosis of superior vena cava
More elevated in one arm than in other and lower or normal in leg veins	Localized obstruction of axillary or subclavian veins due to exertion, pressure from neoplasm, cardiac failure; unilateral chest lesions (pleural effusion, pneumothorax, thoracoplasty); aneurysm of aorta (85 per cent higher on left than on right); aneurysm of innominate artery (higher on right than on left); arteriovenous fistula of arm
More elevated in one leg than in other and lower or normal in arm veins	Arteriovenous fistula of leg; thrombosis of femoral or iliac vein
Dissociation between internal jugular vein and general peripheral venous system	Polycythemia or mass in neck or upper mediastinum (elevated pressure); thrombosis of lateral sinus (diminished pressure)
Elevated in portal vein and normal in arm and leg veins	Cirrhosis of liver; obstruction of portal vein; obstruction of splenic vein; ?Chiari syndrome

*Also observed during abdominal operations.

VASCULAR SURGERY

General Considerations

In Chapter 3 we discussed the mechanisms of repair in various types of tissues and organs, the formation of new capillaries in granulation tissue from endothelial proliferation of the divided capillaries, as well as the restoration of continuity of the endothelium when larger vessels were injured. In Chapter 13 we reviewed the physiology of the circulation, the effects of hemorrhage and plethora, and the reaction of the larger

blood vessels to trauma and methods for the control of such injuries. *In the remainder of this chapter we shall discuss the surgical methods* used in the management of diseases and injuries of the blood vessels and lymphatics. Abnormalities may demand that vessels be ligated, anastomosed, excised, or obliterated.

Ligations

Ligations may be made in continuity. However, ligation and division of an injured vessel is preferable because of the danger of erosion and hemorrhage, or reestablishment of lumen or vasomotor phenomena. The tug on the end of an artery which has been tied in continuity, even though only a fibrous cord remains, may cause pain, poor pulse, or claudication until divided. The local effects of ligation have been described in Chapter 3. However, some facts need to be emphasized. Halsted showed years ago that a silk ligature applied tight enough to obliterate a large artery always cuts the intima and media and this wound *is responsible for the local thrombus.* The diminished pressure and flow within an occluded large artery is also a factor in local thrombus formation. Theoretically, if healing is to occur without thrombosis, intima must be opposed to intima without injury to this layer of endothelium. To achieve this result, bands of fascia (recently cellophane has been employed) are wrapped around the vessels for partial occlusion as often used in carotid incomplete ligation or complete constriction. The partial occlusion reduces the lumen to about 50 per cent and prevents *re-expansion due to fibrosis. If occlusion of the vessel is too great,* the Venturi phenomenon or retrograde flow through collaterals due to the conversion of end pressure of the artery to lateral pressure may cause aneurysmal dilatation peripheral to the narrowing. This same phenomenon is sometimes seen in coarctation of the aorta. The Venturi principle was first described by G. B. Venturi, an Italian physicist (1746-1822), who showed that when there is a reduction in the cross-sectional area of a pipe containing flowing water, there occurs an increase in velocity and a decrease in pressure. The *venturimeter* is an instrument for measuring the flow of liquids such as the blood flow in blood vessels. Since there may be hypertrophy proximal to the stenosis in an artery, the normal vessel distal to the narrowing may dilate due to the sudden increase in lateral pressure as the velocity is quickly slowed. The same caution should be used in doing lateral suture of blood vessels.

For all practical purposes the tying of an artery as usually done produces a thrombus at the site of ligation *which may propagate.* The thrombus forms proximal and distal to the ligature and its propagation is not limited by the nearest sizable branch it may go on.

Effects of Ligations on the Part.—The effect of ligation depends upon the amount of collateral circulation present, degree of vasospasm

engendered, and vulnerability of the tissue. In the final analysis anoxemia of the part is the deciding factor—if the tissues can withstand the decreases in oxygen until collaterals form, they will live. This is the reason for incomplete ligation. The amount of collateral circulation which occurs after tying previously normal major vessels is fairly well known, due to military and civilian experience in injuries which demand ligation, as is also the degree of vasospasm and vulnerability of tissue. A ligature acts as a severe trauma and produces vasoconstriction distally. If, however, the artery is divided between ligatures, or if the sympathetics are interrupted by injection of local anesthetic into the ganglion, or if ganglionectomy is done, vasoconstriction does not occur. Obviously simply dividing the injured vessels between ties is the method of choice; other methods mentioned are used if this fails. However, vasoconstriction should be dealt with promptly. Since cold, pain, fear, anger, asphyxia, hemorrhage, or dehydration are common causes for vasoconstriction, measures are instituted to avoid such factors. Whether ischemia progresses to recovery or not depends upon the volume of blood the limb receives, the pressure at which it is delivered, the length of time the ischemic state has existed, and the metabolic demands of the limb itself. Since re-establishment of circulation depends on collaterals, every ligation should be done with a minimum of trauma and under aseptic conditions. Extensive débridement may cause thrombosis in the collaterals, or a large hematoma may compress them, in either case causing gangrene. Shock due to its lowering of blood pressure may so decrease peripheral circulation as to cause ischemia. For this reason blood transfusion is imperative. Holman believes that a large artery should be tied just beyond a large collateral vessel or branch so that the full force of arterial pressure is used to expand this collateral and its branches. The ligature which is applied distal to the injury is placed just proximal to a large branch if feasible. In general the following disturbances may result from the ligation of large arteries: (1) destruction of tissue varying from local necrosis in muscles (ischemic myositis or Volkmann's ischemic contracture) to gangrene; (2) functional disorders due to reduced blood supply such as intermittent claudication; (3) vasomotor phenomena, trophic disorders, cyanosis, sweating, cold extremities, etc.

The danger of occlusion to the common or internal carotid is that of cerebral damage due to anoxemia which results in hemiplegia and aphasia. This danger is less in the young than in the aged. The innominate and subclavian may be tied without serious effects if exposure is good. The occluded axillary artery may cause gangrene in the lower forearm and hand in the older individual but is less apt to do so in the younger. The ligated brachial is less apt to cause trouble if tied distal to the profunda or the superior ulnar collateral. Ligation of the common, external, or internal iliacs usually do not cause gangrene. The super-

ficial or deep femorals compensate for each other. A tie on the popliteal is followed by gangrene in 70 per cent, ischemic myositis in about 25 per cent—6 per cent escape permanent effects.

Secondary hemorrhage with repeated ligations implies much thrombosis to collaterals and gangrene with possible infection and death. Ligation beneath mucous membranes or near the mouth, nose, anus, or vagina are apt to be infected unless precautions are taken. A good sign at the time of ligation is bleeding from the distal segment of the artery. Tying of the concomitant vein does not improve the chance for recovery but does not hinder it and is therefore commonly done in the hope that collaterals may form more quickly. Even though the distal pulses are absent, a limb will probably survive if active movement of the digits is present and if they are warm, have sensation, and good color. The pulse will return only when the collaterals are wide and short; if narrow and long, *the pulse is not felt because it is lost in its transit back to the main artery.*

Exposure of Blood Vessels.—In accidental wounds, ligations are usually done at the site of the injury. However, the injured vessel may be badly torn and, if large, may not be properly controlled by ligature because of an exsanguinating hemorrhage, or the vessel may be cut and an anastomosis may be indicated; in either event, a temporary or permanent ligature is advisable proximal to the tear. Aneurysm or arteriovenous fistula also demand proximal control—in fact, such control is as essential to successful vascular surgery as the control of spillage in the bowel surgery and certainly more apt to be lethal. Most textbooks on applied anatomy describe the anatomical considerations, involved in ligations. Here we can only outline a few general rules. (1) Although ligations are lifesaving, yet some consideration should be given to the cosmetic result of incisions made for this purpose. Skin creases are followed, not cut vertically, for reasons given in Chapter 3. In the neck a transverse incision heals with a minimum of scarring but such incisions are not always feasible. In the cubital and popliteal spaces the same rule is followed; if insufficient exposure is obtained, then the incision is enlarged by converting the transverse opening into a ⌐—˩ or S- or Z-shaped incision. (2) The base of the neck contains the innominate, subclavians, and carotids. To reach them the clavicle should be removed subperiosteally, wholly or partly, as indicated. If the sternal end is removed, the cartilage should be excised and then a vertical incision *through the periosteum* exposes the innominate and carotid. A wider exposure of the vessels in the superior anterior mediastinum is secured by the Sauerbruch operation or its modifications. The sternum is split down to the level of the third interspace, with Schumacher sternal shears, or the Lebsche sternum splitter or the Bethune bone-cutting forceps, and across into the right and left third interspace and the sternum spread apart. In addition, the inner third of the right or left clavicle or both

may be resected. Through the central portion of the clavicular bed the subclavian vessels and brachial plexus are reached. Division of the scalenus anticus exposes the vertebral at its origin and the thyrocervical trunk. Prolongation of the incision laterally in the groove between the pectoralis major and deltoid leads to the cephalic vein—a guide to the axillary vessels as every surgeon knows who has performed radical mastectomy. (3) The vertebral vessels, according to Elkin, are best described in three parts: (a) the part passing from its origin in the subclavian artery to the foramen in the transverse process of the sixth cervical vertebra is best reached through an incision parallel to the fibers of the sternomastoid muscle and over the interval between its sternal and clavicular heads; (b) the part which runs through the foramina of the transverse processes of the upper six cervical vertebra is exposed through an incision along the anterior border of the sternomastoid muscle which is retracted laterally; the carotid sheath is held aside medially and the scalenus anticus is retracted laterally or divided from its origin on the transverse processes which are exposed and one or more rongeured away; (c) the third part extends from the foramen in the atlas to the occipital foramen. It is exposed through an incision high and parallel with the sternomastoid muscle which is detached from its insertion and turned downward posteriorly. The tip of the transverse process of the atlas is identified and the origin of the levator scapulae muscle is cut and turned down. (4) To approach vessels within the thoracic cage, portions of the first and second ribs with a variable segment of the sternum are removed. (5) The brachial vessels are easily exposed on the medial side of the arm through a cut along the biceps edge and the ulnar and radial through longitudinal incisions on their respective sides of the forearm. (6) The iliac vessels are approached through an incision above and parallel with the inguinal ligament. The peritoneum and abdominal contents are retracted medially. (7) The femoral vessels lie medial to the sartorius muscle in their proximal portion and behind this muscle in their distal parts. An incision medial to this muscle high in the thigh or anterior to it lower down will give good exposure after the muscle is retracted. (8) The anterior and posterior tibial and peroneal vessels are best exposed at their origin by removing subperiosteally the upper portion of the fibula through an incision over it, being careful not to injure the common peroneal nerve. (9) The incision for exposure of the tibial and peroneal vessels lower in their course is made on the medial side of the leg posterior to the tibia. (10) The plantar vessels are approached on the medial side of the foot rather than through the sole, thereby avoiding a scar on the weight-bearing area.

Type of Ligature.—Much has been written concerning ligature material and the respective merits of the material fully reviewed. We have already described the use of fascia for incomplete ligation of large vessels, although metal bands, rubber bands, and cellophane have also been

used for this purpose. In general, it is our custom to use catgut in infected or potentially infected areas—the size of the gut varies with the size of the vessel. We have not found it necessary to use a size larger than No. 1 chromic. Ligations of large vessels are usually best accomplished by using a large size silk (No. 1 or 2) or cotton. We have preferred these sutures because they are more pliable and easier to handle when the vessels are transfixed. For the largest arteries some surgeons use small umbilical tape. We have used this material as a temporary or holding ligature and also as a tie. A single knot is made and the edges sutured with silk or cotton. Then a transfixion ligature is placed distal to this. We are now using large-sized waxed silk and find this entirely satisfactory. The method of ligating is perhaps as important as the material employed. In Chapter 3 diagrams of methods used are depicted; in Chapter 21 the illustration of handling the subclavian vessels in complete disarticulation of the shoulder is depicted. All large vessels are first tied proximally and distally, leaving enough space to put in at least a proximal transfixed ligature. If space allows, two transfixed ties are put in and the vessel divided between them. Transfixion may be accomplished by a single or double suture through the vessel as shown in Chapter 3 or by a purse-string type of ligature as is sometimes used in obliterating a patent ductus arteriosus. In pneumonectomy the pulmonary vessels are dissected out and the branches are tied distally. This leaves a flare distal to the proximal ligatures. Other materials used for ligation are hemp, ox aorta, ox peritoneum, kangaroo tendon, silver wire, etc.

Complications of Ligations.—These have already been mentioned. They may be summarized here as follows: (1) Secondary hemorrhage due to cutting through of ligature, necrosis, or infection. (2) Thrombosis with propagating thrombi leading to embolism or occlusion of collaterals due to various factors such as trauma at the time of injury, extensive débridement, infection, exposure to cold, loss of large volume of blood with resulting hypotension. The organization of a thrombus is facilitated chiefly through the media. The organized thrombus occurs in a regular and concentric form in the young and in an irregular manner in the old. The vessels that invade the thrombus run parallel to it if it is aseptic; if infected the penetrating vessels diverge radially. The inflammatory reaction about a thrombus extends beyond the adventitia of the artery to the walls of adjacent veins and nerves but does not involve the concomitant vein as often as venous thrombosis involves the neighboring artery. (3) Aneurysmal dilatations. (4) Effect on the extremity as previously described.

Anastomosis

The restoration of vascular continuity is desirable wherever and whenever possible. Moreover, if ligation of the vessel is known to carry a great chance for gangrene, anastomosis may be done in the hope that

the extremity will remain viable long enough for collaterals to form, even though ligation will be necessary later. At the outset we must remember that ligation is a lifesaving measure and if a patient has multiple injuries, as is usually the case, or if his condition is poor, anastomosis had better not be tried. There are other contraindications: extensive trauma to a limb which is badly crushed, making restoration of circulation unlikely and resulting in gangrene due to devitalization by the crushing force; a long period of avascularity (experiments tend to show that if an extremity is not warmed, skin will survive at least twenty-four hours; muscle, six to ten hours; nerve tissue less); and lastly, poor hospital facilities. Anastomosis will be found most satisfactory then in incised wounds or bullet wounds seen early with good hospital facilities. However, as a temporary measure, no matter what the condition of the wound itself, anastomosis may be attempted.

Methods of Anastomosis.—Smaller vessels are less apt to stay open than larger ones, but this is not deterrent. The adventitia has no tensile strength; bits of it may be carried into the vessel lumen and therefore it is pushed back and not included in the suture. After suturing is complete, it is worked back over the stitch line, carrying its vaso vasorum with it and thereby nourishing the media. Thus stitches go through intima and media. Sutures should be of fine waxed silk No. 00000 placed close together and may be continuous or interrupted, over-and-over, or mattress. Ideally, the mattress eversion stitch bringing intima to intima with no thread exposed intralumenally is best. Practically any method of suturing is good provided loose ends do not wave in the blood stream, producing thrombosis and the propagation of the clot. Constriction of the lumen may cause a turbulence and a clot peripheral to the constriction which propagates. Torsion of the vessel will have a similar effect.

If ideal conditions do not prevail for direct suture or if the gap is wide, nonsuture methods or suture with mechanical aids should be tried. Various devices have been tried: venous grafts with and without Vitallium tubes; plastic, silver, glass tubes; absorbable cellulose; molded fibrin and gelatin tubes. If a vein graft is used, the distal end of the vein is anastomosed to the proximal end of the artery. Recently Blakemore and colleagues have combined the use of Vitallium tubes and venous grafts with good results in traumatic injuries, restoration of arterial continuity after excision of arteriovenous fistula and after excision of arterial aneurysm, portal-caval anastomosis in portal or splenic hypertension (Laennec's or portal cirrhosis; congestive splenomegaly or Banti's syndrome) and splenic-renal vein anastomosis following splenectomy in Banti's syndrome. The use of anticoagulants such as Dicumarol and heparin has been advocated in venous anastomoses and venous grafts and all tube types of restoration of continuity, whereas their use in arterial suture has not seemed warranted. Heparin subcutaneously as out-

lined in Chapters 6 and 13, keeping the clotting time at about 20 minutes, would seem to be indicated in all graft types of restoration of continuity; however, the danger of hemorrhage probably outweighs the danger of thrombosis and therefore anticoagulants are not universally employed.

CONTUSIONS AND WOUNDS OF ARTERIES

Contusions

Contusions of arteries may be followed by an inflammatory change or *arteritis*. This leads to *thrombosis* and ultimate obliteration of the vessel or embolism. Resection of the contused portion of such an artery may release spasm and aid the cold, blue, painful extremity to become normal again. If seen early, ten to twelve hours, the thrombus may be removed. Spasm of an artery is seen as a temporary effect after contusions, wounds, and fractures. Pulsation is temporarily absent and the extremity becomes cyanotic and cold. This spasm is a compensatory mechanism to reduce hemorrhage and prevent clotting in the vessels which will be required for collaterals. It is unwise to interfere with this process early because collaterals will have their best chance to function when end pressure is increased, forcing more blood into collaterals. Later, should vasoconstriction persist, sympathectomy may be indicated.

Other important considerations of arterial contusion are the secondary effects such as weakening of the arterial wall with subsequent rupture and hemorrhage; pulsating hematoma may follow late rupture and hemorrhage into surrounding tissues with formation of a sacculated false aneurysm. *Concussion* of an artery may produce temporary spasm. In all wounds where contusion or concussion has occurred, careful exploration is indicated. The former requires excision of the contused portion, the latter perhaps a periarterial sympathectomy which is really done to inspect the vessel wall. The introduction of drains in a wound with sutured or ligated large blood vessels is dangerous and should not be done; in fact, no foreign bodies, including the sulfonamides, should be introduced.

Wounds

Wounds of arteries may be complete or incomplete. A complete wound is one which traverses the entire vessel wall. It may be a clean incised wound which may be longitudinal or tangential or transverse. We have noted in previous chapters (Chapters 3 and 13) that the former bleed more freely than the latter, which retract. The wound may be a lacerated one in which a part of the vessel has been torn away. Lastly, the concomitant vein may have been injured. Complete wounds are treated by one of the following methods:

1. Ligation is a lifesaving measure. We have already discussed this procedure previously; however, some facts need emphasis. Ligation and

the extremity will remain viable long enough for collaterals to form, even though ligation will be necessary later. At the outset we must remember that ligation is a lifesaving measure and if a patient has multiple injuries, as is usually the case, or if his condition is poor, anastomosis had better not be tried. There are other contraindications: extensive trauma to a limb which is badly crushed, making restoration of circulation unlikely and resulting in gangrene due to devitalization by the crushing force; a long period of avascularity (experiments tend to show that if an extremity is not warmed, skin will survive at least twenty-four hours; muscle, six to ten hours; nerve tissue less); and lastly, poor hospital facilities. Anastomosis will be found most satisfactory then in incised wounds or bullet wounds seen early with good hospital facilities. However, as a temporary measure, no matter what the condition of the wound itself, anastomosis may be attempted.

Methods of Anastomosis.—Smaller vessels are less apt to stay open than larger ones, but this is not deterrent. The adventitia has no tensile strength; bits of it may be carried into the vessel lumen and therefore it is pushed back and not included in the suture. After suturing is complete, it is worked back over the stitch line, carrying its vaso vasorum with it and thereby nourishing the media. Thus stitches go through intima and media. Sutures should be of fine waxed silk No. 00000 placed close together and may be continuous or interrupted, over-and-over, or mattress. Ideally, the mattress eversion stitch bringing intima to intima with no thread exposed intralumenally is best. Practically any method of suturing is good provided loose ends do not wave in the blood stream, producing thrombosis and the propagation of the clot. Constriction of the lumen may cause a turbulence and a clot peripheral to the constriction which propagates. Torsion of the vessel will have a similar effect.

If ideal conditions do not prevail for direct suture or if the gap is wide, nonsuture methods or suture with mechanical aids should be tried. Various devices have been tried: venous grafts with and without Vitallium tubes; plastic, silver, glass tubes; absorbable cellulose; molded fibrin and gelatin tubes. If a vein graft is used, the distal end of the vein is anastomosed to the proximal end of the artery. Recently Blakemore and colleagues have combined the use of Vitallium tubes and venous grafts with good results in traumatic injuries, restoration of arterial continuity after excision of arteriovenous fistula and after excision of arterial aneurysm, portal-caval anastomosis in portal or splenic hypertension (Laennec's or portal cirrhosis; congestive splenomegaly or Banti's syndrome) and splenic-renal vein anastomosis following splenectomy in Banti's syndrome. The use of anticoagulants such as Dicumarol and heparin has been advocated in venous anastomoses and venous grafts and all tube types of restoration of continuity, whereas their use in arterial suture has not seemed warranted. Heparin subcutaneously as out-

matory changes to develop around the extravasated blood with the formation of a fibrous wall or sac. This is known as a *false aneurysm* since the wall of the sac is made of fibrous tissue. If the adventitia and media have been injured, allowing the intima to bulge, a true aneurysm is formed which contains portions of intima and media. Aneurysm may also result from nontraumatic injury, chief of which is *bacterial invasion.* This is particularly true of the ascending aorta and aortic arch. In general, an aneurysm of the aorta or the largest vessels in the body is usually bacterial; smaller and more peripheral arteries develop aneurysms more commonly from traumatic injury. The *Spirocheta pallida* is the most common offender, causing a syphilitic arteritis late in the disease. The organisms reach the vessel wall through the vasa vasorum, which in turn become obstructed due to intimal proliferation. As a result of this obstruction, the nutrition of the tunica media is impaired, resulting in a degeneration of the muscle fibers and replacement by fibrous tissue which stretches under the lateral pressure exerted by pulsations, causing a fusiform or saccular dilatation. Another type of bacterial damage is seen in mycotic aneurysms. Here an infectious arteritis results from: (1) Local suppurative process (pulsating abscess as seen in suppurating lymph nodes, retropharyngeal, peritonsillar abscess, or abscess anywhere adjacent to a large artery). (2) Tuberculosis or actinomycosis with involvement of the media and aneurysm or even rupture of the artery. (3) Emboli may lodge in the vasa vasorum with the formation of a local abscess in the arterial wall—this mycotic embolic arteritis is seen in subacute bacterial endocarditis, typhoid fever, pneumonia, or other septicemias. Usually mycotic aneurysms are found in peripheral, unprotected arteries (popliteal, femoral, axillary, brachial) but may be seen anywhere. We have seen them in the superior mesenteric and renal arteries in cases of subacute bacterial endocarditis, the former in a girl 10 years of age. It should be added that an aneurysm may itself be the seat of subacute bacterial endarteritis giving rise to emboli. (4) Periarteritis nodosa and other types of necrotizing arteritis in which the medial coat shows localized areas of necrosis may cause aneurysms in small and medium-sized arteries. The causative organisms are not known. Other causes of aneurysm are: (1) Arteriosclerosis. This is the most common cause of aneurysm of the extremities in those over 50 years of age. The localized destruction of the medial coat is probably the result of impaired nutrition from thickening and compression of the vasa vasorum. The arteries have deposits of calcium and are friable which accounts for the fact that arteriosclerotic aneurysms are seen where the vessel is peripheral, unprotected by muscle, and subject to the strain of bending as in the popliteal and femoral regions. We have recently seen bilateral arteriosclerotic aneurysms of the femoral arteries in a man 58 years old with arteriosclerosis. (2) Congenital defects where there is a localized weakness of the media. The intracranial vessels—internal carotid, anterior

division is preferable to ligation in continuity due to the possibility of erosion of the vessel or re-establishment of the lumen through partial necrosis of tissues within the ligature. Also, the danger of vasomotor phenomena and pain as a late complication should be remembered. Ligation of the concomitant vein is strongly urged by some and condemned by others. Those who advocate it aver that the incidence of gangrene is decreased by 12 to 15 per cent. There is a great difference of opinion in various studies of battle casualties. Those who use it claim that reducing the rate of venous return permits better peripheral nourishment by inducing colaterals to form due to an increase in venous, capillary, and arteriolar pressures, respectively. In civilian practice it is wise to ligate the large vein which accompanies the torn artery because it is usually contused, if not torn, and is a fruitful source of thrombosis and possible embolism. If the distal segment pulsates (Henle-Coenen phenomenon), this is evidence of good collateral circulation and the vein need not be ligated. The extremity should not be warmed.

2. Suture repair has also been discussed. Clean wounds involving less than half the circumference give the best results, although any wound seen early may be repaired, using fine silk through all the coats (some authors advise not including the intima; others do not include the adventitia). Heparin should be used for twenty-four hours at least. The size of the vessel may be reduced by one-half and still have 75 per cent of normal blood flow through it.

3. Nonsuture anastomosis with Vitallium, plastic, or glass tubes or vein segments may be tried if facilities are available. Even though unsuccessful, this measure may provide for blood flow long enough to allow collaterals to form, even though later ligation and resection may be necessary. Bleeding from the distal segment is a good sign.

4. Nonsurgical therapy may be used in small wounds of vessels in which hemorrhage may be controlled by pressure. Even though a false aneurysm may form, this can be excised after collaterals form. In addition to the surgical measures outlined, supplemental therapy includes anticoagulants, sympathetic block or sympathetic ganglionectomy, fasciotomy to relieve external pressure, oxygen, and posture (heart level or higher).

Incomplete wounds are more apt to form pulsating hematomas which in time form a false aneurysm. Also, as a result of small incomplete wounds in arteries, true aneurysms occur. If the neighboring vein is also injured, arteriovenous fistula results. Cirsoid aneurysm or aneurysmal varix, while usually congenital, may result from large arteriovenous fistula. In pre-existing vascular nevi, injury may accentuate the lesion and convert a small hemangioma into a plexiform or racemose angioma.

Aneurysms.—Injury to an artery may permit the outpouring of blood into surrounding tissue, forming a hematoma which pulsates. The hematoma temporarily stems the flow of blood, allowing time for inflam-

matory changes to develop around the extravasated blood with the formation of a fibrous wall or sac. This is known as a *false aneurysm* since the wall of the sac is made of fibrous tissue. If the adventitia and media have been injured, allowing the intima to bulge, a true aneurysm is formed which contains portions of intima and media. Aneurysm may also result from nontraumatic injury, chief of which is *bacterial invasion.* This is particularly true of the ascending aorta and aortic arch. In general, *an aneurysm of the aorta or the largest vessels in the body is usually* bacterial; smaller and more peripheral arteries develop aneurysms more commonly from traumatic injury. The *Spirocheta pallida* is the most common offender, causing a syphilitic arteritis late in the disease. The organisms reach the vessel wall through the vasa vasorum, which in turn become obstructed due to intimal proliferation. As a result of this obstruction, the nutrition of the tunica media is impaired, resulting in a degeneration of the muscle fibers and replacement by fibrous tissue which stretches under the lateral pressure exerted by pulsations, causing a fusiform or saccular dilatation. Another type of bacterial damage is seen in mycotic aneurysms. Here an infectious arteritis results from: (1) Local suppurative process (pulsating abscess as seen in suppurating lymph nodes, retropharyngeal, peritonsillar abscess, or abscess anywhere adjacent to a large artery). (2) Tuberculosis or actinomycosis with involvement of the media and aneurysm or even rupture of the artery. (3) Emboli may lodge in the vasa vasorum with the formation of a local al scess in the arterial wall—this mycotic embolic arteritis is seen in subacute bacterial endocarditis, typhoid fever, pneumonia, or other septicemias. Usually mycotic aneurysms are found in peripheral, unprotected arteries (popliteal, femoral, axillary, brachial) but may be seen anywhere. We have seen them in the superior mesenteric and renal arteries in cases of subacute bacterial endocarditis, the former in a girl 10 years of age. Fig 176*b*.—Angiocardiogram showing aortic aneurysm. *A*. Left anterior oblique angiocardiogram at ⅓ second interval showing opacification of superior vena cava (*1*) and right atrium (*2*) Note large density inseparable from vasculature at base of heart (*3*). *B* Left anterior oblique angiocardiogram at 1½ second interval. Superior vena cava (*1*), right atrium (*2*), right ventricle (*3*), inferiorly displaced main pulmonary artery (*4*), right branch of pulmonary artery (*5*), and left branch of pulmonary artery (*6*). *C*. Left anterior oblique angiocardiogram at 10-second interval showing opacification of left ventricle (*1*), aortic conus (*2*), aneurysm of ascending aorta (*3*), descending aorta (*4*) *D*. Left anterior oblique angiocardiogram at 11½ second interval showing more complete filling of aneurysmal sac with opaque dye. Note marked encroachment on aortic window (*1*) with inferior displacement of pulmonary arteries (*2*), and posterior displacement of trachea (*3*). Dicetyl phosphate, 0.9 per cent, in olive oil was used around the aneurysm with resulting fibrosis and great improvement in all of the patient's symptoms (persistent cough, hoarseness, shortness of breath, and pain).

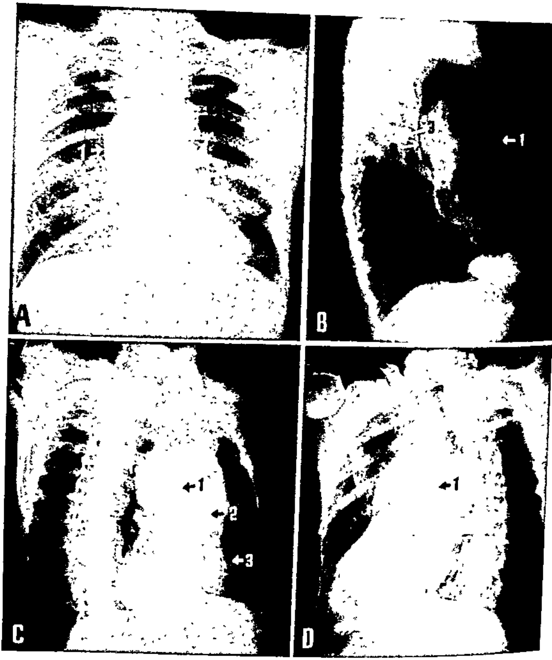

Fig. 176a.—Aneurysm of the ascending arch of the aorta, saccular type. X-ray photographs showing aortic aneurysm. *A.* Posteroanterior teleroentgenogram showing mediastinal mass blending with shadow of ascending aorta (*1*). *B.* Lateral chest film showing large smoothly contoured density in retrosternal area inseparable from ascending aorta (*1*) and compressing trachea posteriorly at (*2*) Note slight vertebral erosion (*3*). *C.* Left anterior oblique film showing loss of aortic window (*1*) double density of mass on ascending aorta (*2*), and projecting anterior border of right ventricle at (*3*). *D.* Right anterior oblique film showing double density of mediastinal mass (ascending aorta) (*1*). This mass is inseparable from aortic shadow in all projections, a finding consistent with aortic aneurysm (see Fig. 176*b*, *A*, *B*, *C*, and *D*).

The teleroentgenograms reveal the presence of a mass which presumably is an aneurysm but which cannot be definitely proved so. Fluoroscopic examination did show pulsations, and this was interpreted as pulsations of the aneurysm. However, this could be transmitted and, therefore, was not positive. Angiocardiograms in Fig. 176*b* definitely prove this opacity to be an aneurysm of the ascending arch of the aorta, saccular in type.

proximal to an aneurysm has no effect on pulse rate or blood pressure, whereas pressure proximal to an arteriovenous fistula or over the fistula causes a slowing of the pulse and an increase in blood pressure. The continuous thrill and bruit and venous engorgement with edema all serve to identify the fistula. Diagnosis of aneurysms is greatly facilitated by angiography and aortography.

Treatment.—Treatment must be directed at removal of the aneurysm or its obliteration by plication and occlusion of new vessels which enter it. In a few cases the continuity of the vessel may be restored. As a rule, the success of the operation in the extremities depends on adequate collateral circulation. Aneurysms of the large arteries of the chest and abdomen require anastomosis as a rule. Rarely sufficient collateral blood supply will form to permit even aortic resection (see coarctation). If the aneurysm involves an artery to a dispensable organ, the organ may have to be sacrificed; namely, kidney, spleen, lung. In vascular injuries, especially if good surgical facilities are not available, it may be wise to allow an aneurysm to form, permitting collaterals to develop, whereas immediate ligation of the wounded vessel may result in gangrene. Obviously this policy cannot be adopted in the face of a rapidly increasing hematoma which threatens the circulation.

The time for operation depends upon adequate collateral circulation even though resection and anastomosis is contemplated. This is true in the latter instance because thrombosis may occur at the site of anastomosis. The development of collateral circulation will usually be advanced enough three months after injury to permit aneurysmal extirpation. However, in nontraumatic and traumatic types various methods are employed to facilitate the development of collaterals. These methods may be listed under the following headings: (1) Chemical. Drugs, such as whiskey, acetylcholine, papaverine, tetraethylammonium chloride or bromide, Priscoline hydrochloride, and cessation of smoking may be tried. (2) Nervous. Interruption of sympathetic action by injection of 1 per cent Novocain daily into the ganglia or preferably by their surgical extirpation or repeated caudal blocks may be used. (3) Mechanical. Measures such as intermittent occlusion of the artery, by hand compression or with the aid of mechanical devices, is often useful, as is also incomplete ligation with fascial band used chiefly in the cerebral aneurysms which demand occlusion of the common carotid artery. This last method is used whenever a large artery is tied for the removal of an aneurysm; that is, the ligature is not pulled snug at one time—three to five minutes are allowed to complete the procedure. This brief interval permits some readjustment on the arterial and particularly the venous side which, due to arterial vasoconstriction, allows venous stasis to occur, thereby suddenly trapping a large quantity of blood in the extremity.

Tests for collateral circulation before surgery are many and varied. Matas suggested compression of the artery proximal to the aneurysm.

portion of circle of Willis—are the most common sites. Rarely they rupture, causing intracranial hemorrhage in the young. Other vessels are rarely involved.

Aneurysms, traumatic or otherwise, therefore may involve any artery in the body. In addition to false and true varieties as previously defined, the pathological types are known as (1) fusiform, which cause a general or uniform dilation of a segment of the artery, (2) saccular, in which there is an outpouching of the vessel wall, and (3) dissecting, which causes a cavity between the layers of the arterial wall due to rupture and which dissects its way between the layers, rupturing to the outside or back into the lumen of the vessel at a distant point.

The symptoms and signs will vary with the type and location of the aneurysm. In the brain, small aneurysmal dilations give no symptoms or demonstrable signs, whereas large ones resemble a brain tumor. In the thorax they may mimic a mediastinal tumor, which indeed they are. Pain from erosion of vertebrae, ribs, or sternum, cough and dyspnea from pressure on the trachea and bronchi, hoarseness, and "goose" cough from recurrent laryngeal nerve pressure are symptoms of progressive pressure of the aneurysm. Signs of aortic regurgitation may occur when the ascending aorta is involved but without cardiac hypertrophy as in arteriovenous fistula. Innominate, carotid, and subclavian aneurysms may be seen and felt usually and cause sensory and motor changes in the arm due to pressure on the brachial plexus and Horner's syndrome from pressure on the cervical sympathetics. Vertigo and syncope result from carotid aneurysms. In the abdomen the chief symptom is pain. In thin people a pulsating mass may be felt.

Aneurysm of an extremity presents an expansile mass which may disappear when pressure is made on its proximal side. The blood pressure distal to the aneurysm is lower than in similar locations elsewhere. Sometimes there is interference with venous and lymphatic return resulting in edema and muscle anoxemia on exercise; therefore, intermittent claudication may result. Rarely there is redness, heat, and tenderness over a true and especially a false aneurysm so that a local inflammation is suspected. The expansile pulsation and interrupted systolic or diastolic or biphasic bruit on auscultation will usually give the clue. However, this is often attributed to transmitted pulsation and compression of the underlying vessel. Not infrequently both conditions are present—that is, an abscess which eroded or weakened the vessel wall to such a degree that an aneurysm has resulted; on incision, after pus has been evacuated, there may be a sudden devastating hemorrhage; therefore simple aspiration is done first.

Pulsating vascular tumors may resemble an aneurysm and arteriovenous fistula is often mistaken for one.

Before any treatment is instituted, an arteriovenous fistula should be ruled out because ligation proximal may embarrass the circulation further or interfere with the circulation of the extremity. Pressure made

Fig. 177.—Diagrams illustrating methods of treating aneurysms. *A*. Older methods. (*1*) Method of Antyllus, third century A. D. The aneurysm was ligated proximally and distally and the sac was opened and packed with lint. This method produced some cures. (*2*) Method of Annell. This operation was first performed about 1710. The ligation is on the proximal side of the sac. As can be seen, collaterals form very quickly and the aneurysm is not cured. (*3*) The method of John Hunter. This was first reported about 1786. The ligation is proximal at a distance from the sac. It can be easily seen that such a method would lend itself to reformation due to collaterals. (*4*) Method of Brasdor. This was reported about 1760. It consists of ligation distal to the sac before any branches are given off. This frequently failed to produce a cure. (*5*) Wardrops modification of the Brasdor operation consisted of tying one of the branches of the artery beyond the aneurysm. This method also failed to produce a cure.

B. Method of treatment of aneurysm from within. The operation is known as endoaneurysmorrhaphy. It was first described by Matas in 1889 and consists of opening the sac and tying off all the collaterals from within and then obliterating the sac. There are three varieties of this operation which Matas reported at that time. One is called the obliterative endoaneurysmorrhaphy without arterioplasty. This is the operation in which no regard is had for restoration of the continuity of the blood vessel, the collaterals taking care of the circulation to the extremities. (*1*) The openings of entrance and exit of the vessel and all collateral openings are closed. (*2*) The second row of sutures begins the obliteration of the fusiform sac. (*3*) Final sutures which completely obliterate the sac. The second is known as endoaneurysmorrhaphy with partial arterioplasty. This is indicated in the saccular types of aneurysms in which there is one opening between the vessel and the sac. (*1*) The opening is closed and the vessel is allowed to remain patent. (*2*) The sac is then imbricated or extirpated, as the case may be.

C. The third variety is endoaneurysmorrhaphy with complete arterioplasty. This operation seeks to restore arterial continuity, a new channel being made out of the sac walls by simply folding these walls over a rubber guide or tube and suturing them firmly together so that the continuity of the artery is maintained. The catheter is withdrawn, of course, before the final sutures are placed. A diagram of what might be considered the modern concept of this operation is shown in (*1*), where a vein graft is placed within the lumen of the sac, and this is sutured to the opening of entrance and the opening of exit and (*2*) complete excision of the sac with vein graft in place.

D. Arteriovenous fistula with aneurysm. This may be treated by transvenous obliteration of the opening and then imbrication or extirpation of the aneurysmal sac. (*1*) The vein is ligated above and below the fistula. (*2*) The opening is closed without the occlusion of the artery. (*3*) The sac is obliterated. This method is also useful in the treatment of false aneurysms. Here the artery is temporarily occluded, the sac is opened, the opening in the artery closed, and the sac is obliterated. This method is known as transsaccular obliteration.

E. Methods of treating aneurysms of the aorta. (*1*) Wiring. The introduction of wire was first used by Moore of London in 1864. The details were improved by Corradi in 1879. The earlier attempts were to use wire through a small hypodermic needle (the wire was either gold or silver) and then electric current was employed using about 40 to 80 milliamperes. Today electrolysis is not often used. Wiring is useful in the saccular types of aneurysm. (*2*) Wrapping the aneurysmal sac with cellophane or Polythene film. Here the mediastinal pleura is lifted up and the sac is wrapped partially or completely if possible with Polythene film. The mediastinal pleura is closed over the wrapping (*3*) Periaortic injection with dicetyl phosphate. This method consists of injecting 9/10 of 1 per cent dicetyl phosphate in olive oil. Since the dicetyl phosphate is probably the active ingredient in the Polythene film which produces fibroplasia, this method seeks to produce the same effect without the danger of uncovering the aneurysmal sac.

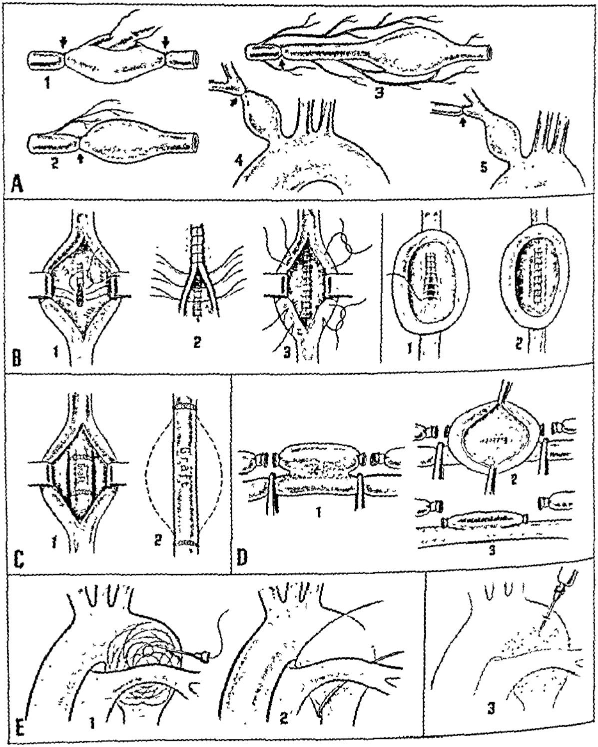

Fig. 177.—*See opposite page for legend.*

dissection can be safely done, inside suture and tamponade may be used or the latter alone where the patient's condition demands immediate cessation of the operation.

Carotid aneurysms of the carotid or its branches are treated by proximal ligation in stages. If feasible, extirpation or obliteration is carried out. Ligation of the common carotid in vertebral artery aneurysms makes them worse. Innominate aneurysms are difficult to treat. The surrounding adhesions make the procedure dangerous and, at times, forbidding. The Matas operation is not useful here. Ligature and removal have been done in only three reported cases, and they were all successful. "Triple" ligation is curative. This consists of proximal ligation of the innominate with ligation of the carotid and subclavian. The carotid should be ligated first to test cerebral circulation, promote collateral development, and prevent subsequent cerebral embolism or propagating thrombosis following operation on the aneurysm in which cerebral complications are common. Distal ligations alone have resulted in cures. Internal mammary and intercostal arteries if injured may form false aneuryms presenting subpleurally or intrapleurally. Syphilitic aneurysms of the aorta and other large vessels have been successfully treated by lifting the pleura or peritoneum covering most of the surface of the aneurysm with Polythene film or injecting the fibroblastic substance of Polythene-dicetyl phosphate around the aneurysm.

Moore, in 1864, introduced the method of producing a clot in the aneurysm by means of wire introduced within the sac. Corradi, in 1875, suggested the use of silver wire introduced through a hollow needle. The protruding end of the bore wire was then connected to the positive pole and the negative electrode was applied to the skin in the neighborhood and a galvanic current passed. Recently this method has been revived for use in large syphilitic and arteriosclerotic aneurysms. Wire used is fine (34 gauge B. & S.), insulated coin silver or 30- gauge stainless steel. This in itself will produce clotting. Blakemore advocates the use of silver wire in 10-meter segments heated to 80° C. by using approximately 100 volts of direct current. "Brimful" clotting is dependent on an adequate and efficient clot-stimulating surface to the passing blood. To accomplish this a means of measuring blood flow in the aneurysm is necessary to know how much wire to use. This is measured by noting the number of amperes required to raise the temperature of the wire 15° C. When one or more segments of wire, well distributed within a saccular aneurysm, requires only 3 amperes to heat the wire to 80° C., mass clotting of the aneurysm takes place. Unheated wire produces gradual occlusion and has been used proximal to the origin of the aneurysm, whereas heated, insulated wire produces quick coagulation, thereby producing endoarterial occlusion and electrothermic coagulation. Although wire was originally introduced blindly with the aid of the fluoroscope through a small nick in the skin, this method has been

If the pulse could be obtained distally or if the extremity remained pink and warm, collaterals were ample. This test may be misleading if pressure is made upon a principal collateral which may be very close to the aneurysm.

Oscillometric readings may help; elevation of the extremity 30 to 40 degrees may be of value. If it remains pink, circulation is adequate; if cyanosis occurs, it is questionable; and if white, it is inadequate as a rule. At the time of operation the best test is bleeding from the distal artery or pulsation after ligation of the proximal portion (Henle-Coenen phenomenon).

The treatment of aneurysm is old. Compression, injection of sclerosing agents, and ligations were used. Antyllus (fourth century A.D.) ligated above and below the sac, opened it, and packed it; Anel (1710) ligated the proximal artery close to the sac; Hunter (1760) tied the femoral artery high in Hunter's canal. All of these procedures failed because of infection, hemorrhage, gangrene, or recurrence. Brasdor (1760) advised ligation distal to the sac. This may be successful if there are no branches between the aneurysm and the distal ligation and is therefore used occasionally in the treatment of aortic, innominate, iliac, carotid, and subclavian aneurysms.

Matas, in 1888, advised opening the sac and occluding all openings and then obliterating it by successive layers of sutures—obliterative endoaneurysmorrhaphy. A sacculated aneurysm may be treated by restorative endoaneurysmorrhaphy; that is, opening of the sac, closure of the communicating aperture, and imbrication of the sac, permitting the arterial lumen to remain patent. If collateral circulation is poor, reconstructive endoaneurysmorrhaphy may be tried—this consists of obliteration of openings into the sac and the main arterial entrance and exit and imbrication around a tube which is removed before final closure. Even though thrombosis ultimately occurs here, collaterals will have been stimulated by the procedure. Matas' operation is easy and safe. With a tourniquet in place or control by proximal and distal tape, the sac is opened and the laminated clot removed; surrounding structures are not molested. This is important because of perivascular adhesions. If the sac is dissected loose, nerves, collateral vessels, and veins may be injured.

Wherever feasible, proximal and distal ligation with excision of the sac is preferred. If the vessel wall is normal, as in traumatic aneurysm, excision may be followed by direct end-to-end anastomosis. Obviously this is most desirable. Large aneurysmal sacs may be aided in their obliteration by using pedicled or free muscle transplants sewed over the inside openings. Muscle adheres to intima by the development of a proliferative endarteritis and recanalization does not occur. This is done in addition to ligation whenever the latter is feasible. In cases where no

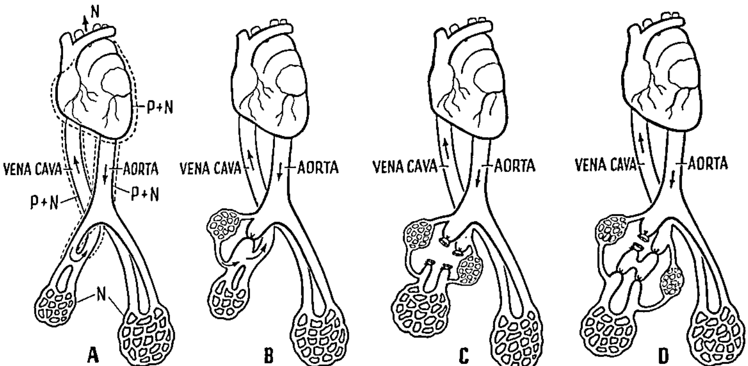

Fig. 178.—Arteriovenous fistula. Diagrams illustrating arteriovenous fistula and its effects. (Redrawn from Holman: Ann. Surg. 122: 210, 1945.) *A*. Shows the fistula and the effects of the parasitic circulation as a result of which there is a dilation of the circulatory bed to transport the increased blood volume. *P*. Parasitic circulation. *N*. Normal circulation. *B*. The effect of ligation proximal to the fistula. Due to the lesser resistance of the fistula, the blood goes back without circulating through the peripheral vascular bed, thereby causing gangrene. *C*. Operation by which the fistula is entirely excised. Ligation of the artery and vein and division proximally and distally. This is the operation of choice. *D*. In cases where this is not possible, an alternative method may be employed whereby there is proximal ligation and division of the artery and ligation of the distal portion of the artery, and ligation of the vein proximally and distally. This quadruple ligation has the same effect as extirpation except that it must be made impossible for recanalization to occur. After quadruple ligation, some form of endoaneurysmorrhaphy may be done whereby the sacs may be imbricated by sutures. The difficulty with the operation of choice is that very often there is danger of injury to important nerves and contiguous structures when the entire arteriovenous fistula in excised.

abandoned except for those aneurysms very close to the skin. It is preferable to open the thorax or abdomen instead of blindly using a trocar through the back in the latter or through the anterior chest in the former. Hydrolyzed polyvinyl acetate and other compounds have been used in the wire for their tissue-irritating effects.

We have recently employed dicetyl phosphate which is the active ingredient on Polythene film which produces fibrosis. This substance has been injected in dogs beneath the mediastinal pleura and peritoneum surrounding the thoracic and abdominal aorta. Dense fibrosis ensues.

Arteriovenous Anastomoses, Aneurysm, and Fistula.—In some regions arterioles communicate with venules; for example, skin of palm of hand and terminal phalanges, the nail bed, skin of lips, nose, tongue, eyelids, and tip of tongue. This is an addition to the capillary communication.

The placenta through the chorionic villi is an example of a physiological arteriovenous fistula; it is true in utero and produces more symptoms as a result of the shunt if the pregnancy is intra-abdominal. Congenital anomalies such as a patent ductus arteriosus or large hemangiomas, particularly in the liver, are examples of a direct communication between artery and vein. Great hyperplasia and hypertrophy of vascular organs constitute another type of arteriovenous fistula; this phenomenon may explain some of the symptoms in exophthalmic goiter. (Chapter 22.)

The term arteriovenous aneurysm is used to describe an arteriovenous fistula with a surrounding sac. Congenital arteriovenous fistulae are also termed pulsating angioma, cirsoid aneurysm (which may be traumatic), simple angioma, varicose aneurysm, cavernous angioma, aneurysm by anastomosis, arteriovenous varix, aneurysm or angioma arteriole serpentina, plexiform angioma, and angioma racemosum.

The etiology may be congenital or acquired. In the latter a penetrating wound by a knife or bullet is the usual cause; where shotgun shells are used, there may be more than one communication. We have had a case with three openings due to buckshot. Bacteria may be the cause, as by embolism with erosion.

Perhaps the most interesting, though rare, malformation is a traumatic connection between an artery and vein. Blood is shunted across from the former to the latter, forcing the unprepared vein to carry arterial blood. If superficial, a pulsating mass and systolic thrill are felt. Also a systolic bruit can be heard. If the carotid artery and jugular vein are involved, the patient can hear the "swish." Great enlargement of the part occurs, with cyanosis due to passive congestion (and the accumulation of reduced hemoglobin) and edema, with resultant fibrosis, eczema, ulceration, and even gangrene. The extremity usually is larger and longer and warmer than the other, unilateral varicose veins are present, and there is chronic venous insufficiency. The distinctive features of a

substance originating in ischemic tissues (Lewis) or due to the theory that blood supply increases with "tissue needs" (Reid). If the distal artery and its branches are patent, collaterals form due to retrograde flow. Moreover, collaterals may be prevented from forming by ligating the artery just distal to the fistula, leaving no branches between the fistula and the site of ligation. The application of a band on the artery proximal to the fistula prevents dilation of the artery by limiting the volume flow of blood through it. The application of a band on the vein proximal to the fistula causes great edema.

End pressure in an artery is determined by peripheral resistance. The greater the end pressure, the greater will be the lateral pressure which is directed into the branches of the vessel. Since end pressure in the artery of an arteriovenous fistula is greater than that at the site of the fistula, blood will be diverted into the vein where resistance is low as compared to the capillary bed distal to the fistula. Moreover, the distal arteriolar and capillary beds will have a great reduction in pressure as compared with the arteriolar and capillary bed proximal to the fistula. Due to this low pressure, blood will be attracted from the proximal to the distal arteriolar and capillary beds, resulting in an increased flow through the corresponding collateral vessels which open up and become dilated in response to this increased flow.

6. Occasionally the artery distal to the fistula is dilated. This is due to an occlusion of the proximal artery by thrombosis with fibrous tissue healing. The site of diminished peripheral resistance attracts blood from all collaterals which in turn connect with branches of the artery distal to the fistula. The resulting, greatly increased volume of blood flowing back through the distal artery causes its dilation.

7. Closing the fistula produces dilatation of the already dilated heart, the aorta, and all of the vascular system as shown by roentgenological kymography (Holman). The dilated aorta stimulates depressor vagus fibers, causing a slowing of the pulse. Perhaps this is augmented by the carotid sinus reflex as well. Atropine eliminates this response showing its vagus origin.

8. Elimination of the fistula permanently is followed by a reduction in blood volume through loss of plasma as shown by increased urinary output and hemoconcentration for a brief period. This results in a decrease in the size of the heart except for the slight hypertrophy which took place during the life of the fistula.

Treatment.—The treatment of arteriovenous fistula may be an emergency. If hemorrhage continues after bed rest and pressure bandage, immediate ligation and division of the vein is done to avoid the danger of embolism from air or thrombus and to improve collateral circulation. The hole in the artery is then closed either by lateral suture or resection and suture. If suture is impossible, then ligation and division of the artery and vein above and below must be done. The blood

fistula as compared with an aneurysm are a continuous thrill and bruit exaggerated during systole; slowing of pulse and rise in blood pressure on digital closure of the proximal artery or fistula; high oxygen content of venous blood. As a result of lowered peripheral resistance and increased venous return, there is cardiac acceleration. The heart must pump an increased volume of blood and therefore dilates and hypertrophies.

Pronounced circulatory effects often follow with dyspnea, tachycardia, palpation, syncope, and even death. This remarkable lesion has led to some very interesting observations on the altered physiology which are explained by Holman as due chiefly to the introduction of a new circulation parasitic upon the normal circulation. A study of available experimental and clinical observations leads to the following deductions:

1. There are two circulations—the normal and the parasitic. The latter differs from the former in that it lacks a capillary bed and substitutes an opening between artery and vein. Each system needs blood and gets it. When the parasitic circulation attracts more than the normal, the patient dies.

2. The effect of this blood diversion is like that of neurogenic shock with (1) a lowering of blood pressure, (2) with a lowering of blood pressure, accelerated pulse, temporary reduction in size of the heart and the artery proximal to the fistula.

3. A redistribution of blood and fluid from the spleen, liver, and tissue spaces soon occurs which restores the pulse and blood pressure to normal. Due to this accretion of fluid and blood there is an increase in blood volume which, when redistribution is complete, circulates through the normal and parasitic systems.

4. Dilatation of the heart and the circulatory bed through which the short-circuited blood passes results due to the increased blood volume. The reverse is true in patients with shock due to loss of blood volumes—that is, the heart and vessels decrease in size. Dilation of the fistulous circuit is due to the fact that there is less peripheral resistance in these vessels which do not go through a capillary bed; and since blood flows through the path of less resistance, more and more blood from the rest of the circulation occupies this parasitic circulation. This diminished blood volume in the rest of the circulation attracts more fluid and blood into fill the vascular tree. Thus there is a gradual but progressive increase in total blood volume.

5. The determining factor in this gradual dilatation is the extent of the difference in peripheral resistances in the two circuits. This, in turn, is determined by (1) the size of the fistula, (2) its proximity to the heart—the nearer the heart the greater the discrepancy in peripheral resistances and vice versa, and (3) amount and firmness of fibrous tissue around the fistula. Collaterals were thought to form due to a chemical

Many operations have been tried and have failed: (1) Ligation of the proximal artery will cause more blood to pour through the fistula and less to go through the peripheral capillary bed as previously explained, causing gangrene of the extremity. (2) Ligation of artery and vein proximally does not cure because collaterals will supply blood to the fistula, although this operation may be used as a preliminary step to extirpation. (3) Ligation of the large veins above and below will simply cause collaterals to fill up the dilated venous system with blood and deprive peripheral capillaries at the same time, increasing venous varicosities. (4) Ligations proximal and distal to the vein and artery are useful as a preliminary—recurrences do occur due to reopening of the proximal artery.

Many operations have been found useful: (1) Transvenous or transsaccular closure (Matas-Bickham). The vein is opened under tourniquet control, the opening or openings in the artery closed, and the vein ligated above and below the rent and its wall used to reinforce the suture line in the artery. (2) Ligation of the artery and vein proximal and distal to the fistula *with division of the proximal artery* where dissections are impossible due to dense fibrous adhesions to nerves. (3) The same as (2) with endoaneurysmorrhaphy, especially if arteriovenous aneurysm is present. (4). The best procedure is ligation of the artery and vein proximally and distally and excision of the fistula. (5) Rarely (4) may be done with anastomosis of the resected artery, thus assuring ample blood supply. This is necessary because in some cases in spite of ample collateral circulation the extremity shows some atrophy and disability with vasomotor changes after excision. (6) Arteriovenous fistulae of the face and scalp have intracranial origin in about 75 per cent of the cases and are usually congenital. The middle meningeal artery on one or both sides provides the arterial supply. Rarely the external carotid or its branches provides the main arterial branch. Careful x-ray study and neurological examination should be done in all cases because the aneurysms or fistulae may involve the brain as well as the dura. The best *treatment* is excision of the primary angiomatous mass. If this is in the dura, the vessels penetrating the bone should be waxed after the scalp has been stripped from the affected area. Sometimes dural varices must be exposed and ligated or coagulated and the middle meningeal artery (one or both) tied. Ligation of the external carotid may be necessary or both external and internal may be required. If in doubt one should expose the common carotid and place a tape around it so that he has control—we have felt that ligation of the common carotid is less dangerous than ligation of the internal carotid. Some authorities advise ligation of the internal jugular vein at the same time (Makins).

The closure of an arteriovenous fistula may raise the systolic and diastolic pressure to such a degree that acute cardiac failure may result. In this event the blood pressure would fall and the pulse rate rise. Vene-

pressure must be kept up by antishock measures—chiefly, repeated massive blood transfusions. Sympathectomy (chemical or surgical) has been advocated by many. Recent studies from extensive war experience do not substantiate its value in all cases.

In the presence of infection or a small wound or one without excessive bleeding, operation may be deferred five to six months to allow for collaterals to form and in the hope that a small fistula may close spontaneously; also the danger of infection will be less and dissections will be easier.

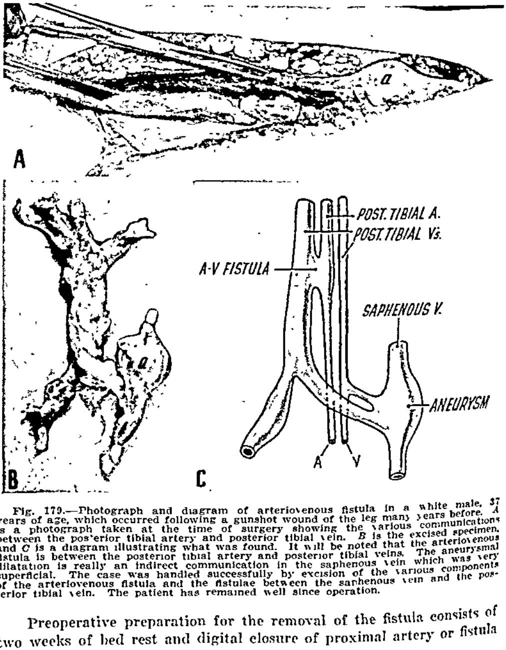

Fig. 179.—Photograph and diagram of arteriovenous fistula in a white male, 37 years of age, which occurred following a gunshot wound of the leg many years before. *A* is a photograph taken at the time of surgery showing the various communications between the posterior tibial artery and posterior tibial vein. *B* is the excised specimen, and *C* is a diagram illustrating what was found. It will be noted that the arteriovenous fistula is between the posterior tibial artery and posterior tibial veins. The aneurysmal dilatation is really an indirect communication in the saphenous vein which was very superficial. The case was handled successfully by excision of the various components of the arteriovenous fistula and the fistulae between the saphenous vein and the posterior tibial vein. The patient has remained well since operation.

Preoperative preparation for the removal of the fistula consists of two weeks of bed rest and digital closure of proximal artery or fistula for one-half hour every two hours.

The thin-walled vessels and sinusoids may be very large and pulsating (cirsoid aneurysm). Cavernous hemangioma may be found in any organ or structure in the body. We have seen them on the face, scalp, neck, buttocks, oral mucous membrane, liver, bone, synovial membrane, muscles of the legs, stomach, intestine, rectum, and broad ligament. The treatment is ligation of the vessels and surgical excision in stages, if large, followed by skin graft if on the skin. If its removal impairs the blood supply to an organ, the organ may have to be removed. For the superficial varieties, electrocoagulation, radium, x-ray, and sclerosing solution have been advocated. Hemangiomas may disappear due to spontaneous

Fig. 181.—Angioma racemosum (cirsoid aneurysm). The patient is a woman aged 24 years. In an automobile accident nine years previously she was cut with glass in the right temporal region. The present condition began six months later and gradually increased in size. An arteriovenous fistula was found between the temporal artery and the vein. This was cured by ligation of the external carotid and excision of the dilated vessels. Ligation of the common carotid artery may be fatal or may cause hemiplegia; therefore, the artery is occluded in stages.

complications such as thrombophlebitis; hematoma due to trauma or spontaneous; erysipelas, nonspecific infection. Some disappear without treatment or complication. Therefore, they are watched and if growth is progressive they are removed before they become very large.

2. Racemose or cirsoid aneurysm resembles an hemangioma, which it may be. This has already been discussed under arteriovenous fistula.

3. Diffuse systemic hemangioma is like a combined capillary and cavernous type involving a large area like an entire extremity. There

section would help by reducing blood volume temporarily to allow for readjustment. Following the operative closure of the fistula the patient's activities should be restricted for six to eight weeks.

TUMORS OF BLOOD VESSELS

Under the term tumor may be included various types of swellings, abnormalities, and neoplasms which involve blood vessels or endothelium. These include the following entities:

1. Hemangiomas are benign tumors, congenital in origin, made up of newly formed blood vessels which grow as do newly formed blood vessels in granulation tissue; namely, solid cords of endothelial cells which become canalized and communicate with parent vessels. There are two kinds of hemangioma (nevus or birthmark)—*capillary* and *cavernous*.

Fig. 180.—Cavernous hemangioma of the face The distribution is roughly that of the ophthalmic and maxillary divisions of the trigeminal nerve.

The flat "port-wine" marks on the face that blanch on pressure represent the *capillary* type. Sometimes they cover one-half of the child's face; often they are only the size of a dime or quarter; they are commonly called nevi (birthmarks). They are due to an abnormal number of small capillaries, which are known to follow roughly the course of nerves. The type called strawberry nevus is more circumscribed and slightly elevated. They are sometimes found with fibromas (hemangiofibroma) or fatty tumors (hemangiolipomas). Hemangiolymphangiomas are seen occasionally. The *treatment* is radium, x-ray, or carbon dioxide "snow."

A cavernous hemangioma (nevus cavernosus, cavernoma) is a large collection of venules and arterioles. It is elevated due to connective tissue about the vessels, and usually has a principal artery and vein.

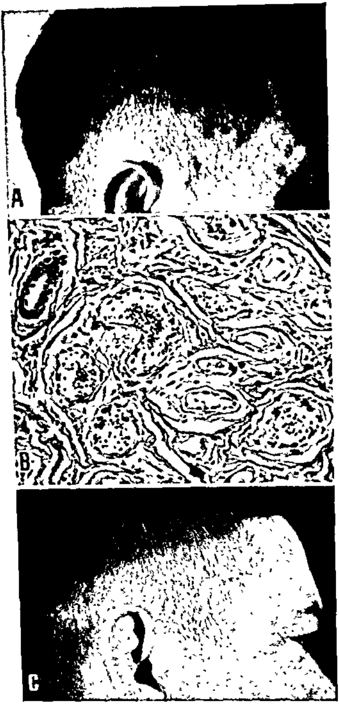

Fig. 183.—Hemangioendothelioma. *A*. Clinical photograph of the patient prior to operation. E. M., forty-five years previously, complained of a swelling in front of the ear and many smaller tumor masses throughout the right portion of the scalp. This proved to be an aneurysm of the temporal artery and multiple endotheliomas of the branches of the temporal artery. *B*. Photomicrograph of sections of the excised tissue (medium power) showing blood vessels of capillary size and of somewhat larger caliber. Note the thickened and edematous walls, the large cells, and occasional mitotic figures. (Case of Dr. H. Pandolfo, Dr. D. Kelly, and Dr. J. Dalton.) *C*. Postoperative clinical photograph after the aneurysm had been removed and the endotheliomas excised. In order to avoid complications, a temporary ligature was placed around the common carotid artery because it was feared that there might be intracranial connections. This did not prove to be the case.

is tissue hypertrophy due to the abnormal blood supply. Sometimes there is great shrinkage on elevation, revealing congenital absence of bones or deformities. Treatment is unsatisfactory. Ligation of the greater and lesser saphenous veins with retrograde injection may be helpful but is not curative as a rule. Excision in sections with skin graft is best.

Fig. 182.—Diffuse systemic hemangioma (combined capillary and cavernous types) of the entire right lower extremity. The child was 2 years old on admission to the hospital. The lesion was present at birth and had grown rapidly. Treatment with x-ray was not successful. X-ray examination showed no bone involvement. Stage operations were planned to remove small areas at a time followed by immediate skin grafts. The child's parents would not consent to surgery.

4. Hemangioendothelioma is a malignant neoplasm with proliferation of endothelial cells. Hemangiosarcomas have, in addition to vascular tissue, fibroblastic connective tissue. Angioblastic or hypertrophic hemangioma are solid elevated masses of endothelial cells with a few patent vessels. These do not metastasize but do tend to recur locally after removal. Metastasizing hemangioma is very rare; it has been re-

Fig. 183.—Hemangioendothelioma. *A.* Clinical photograph of the patient prior to operation. E. M., forty-five years previously, complained of a swelling in front of the ear and many smaller tumor masses throughout the right portion of the scalp. This proved to be an aneurysm of the temporal artery and multiple endotheliomas of the branches of the temporal artery. *B.* Photomicrograph of sections of the excised tissue (medium power) showing blood vessels of capillary size and of somewhat larger caliber. Note the thickened and edematous walls, the large cells, and occasional mitotic figures (Case of Dr H. Pandolfo, Dr. D. Kelly, and Dr. J. Dalton.) *C.* Postoperative clinical photograph after the aneurysm had been removed and the endotheliomas excised. In order to avoid complications, a temporary ligature was placed around the common carotid artery because it was feared that there might be intracranial connections. This did not prove to be the case

ported in the breast with metastases to the lung, yet it appears microscopically *as a benign tumor. Hemangioendothelioma* of bone (Ewing's tumor) is a special type seen in the shaft of long bones in young individuals. Usually hemangioendotheliomas *grow slowly and metastasize* late—some are very malignant. Treatment consists of wide excision if possible, x-ray treatment if not, or perhaps both may be indicated. A leg may have to be amputated if x-ray treatment fails.

5. Telangiectasis is an acquired dilatation of capillaries and small venules. (1) Spider nevus (nevus araneus) is a very small lesion with a pinhead size and radiating tiny capillaries. (2) Senile ectasia (senile vascular nevus) is a raised lesion slightly larger than the spider nevus. These may be removed by fulguration. (3) Hereditary hemorrhagic *telangiectasia (Rendu-Osler-Weber's syndrome) is characterized* by multiple telangiectatic lesions of the skin and mucous membranes with a tendency to bleed. The disease is familial and is said to be inherited

Fig. 184.—*Macroglossia due to hemangioma.* The condition improved under radium treatment.

as a dominant characteristic. The lesions are flat and are red or purple and blanch on pressure from a glass slide. Due to the frequent hemorrhages, patients become anemic. The lesions may be distinguished from petechiae or purpuric spots by their tendency to blanch on pressure and their peculiar distribution (nasal and oral mucous membrane, hands and face); from *hemophilia* by the prolonged *coagulation* time in this disease; from thrombocytopenic purpura by the low platelet count, prolonged bleeding time, and bleeding from gastrointestinal tract more often in purpura; from aplastic anemia by a decrease in platelets, increase *in* bleeding time, and clot retraction time in aplastic anemia; from acute leucemia by leucocyte differential and total counts and by *splenomegaly* in acute leucemia. The *treatment* consists in stopping bleeding by pressure or *fulguration of the lesion and repeated* transfusions. (4) Pulsating telangiectasis resembles spider nevi which pulsate. They are probably minute hemangiomas and seem to be associated with liver diseases. They may be removed by fulguration.

VEINS

A dilatation of the superficial veins may occur as a result of arteriovenous fistula and hemangiomas, conditions which we have discussed. More commonly there is some obstruction to the venous return either due to cardiac failure or some impediment to the flow of blood back to the heart; in the latter instance the veins distal to the obstruction will be dilated, and, in addition, many new or collateral veins will appear which are also very large and unnatural. Perhaps even more often there is a congenital defect in the valves of veins which permits them to dilate and become tortuous; these usually appear in the legs and are known as varicose veins.

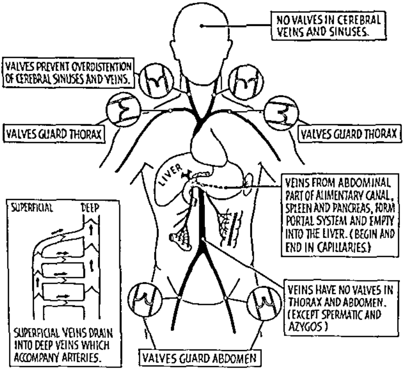

Fig. 185.—Diagram illustrating the valves in veins. There are practically none in the abdominal and thoracic veins. The pressure in the thoracic veins, though low, is greater than the pressure in the thoracic cavity (which is negative), permitting blood to flow into the right auricle. Variations in position and pressures within the thorax and abdomen may thus affect the venous return Insert shows flow of blood from superficial to deep veins, with valves preventing reflux.

Varicose Veins

The latin *varus* means crooked and *varicosus* means dilated or enlarged vein. *Saphenous* comes from the Greek, meaning manifest. Varicose veins are dilated, crooked veins usually seen in the saphenous veins of the legs.

There is a deep set of veins lying in the muscles and a superficial set lying under the skin. In the leg the deep vein is the femoral vein, and the superficial veins are the great and lesser saphenous veins. The

deep veins are surrounded and supported by muscles. But the long or great saphenous vein lies unsupported just beneath the skin. Blood flows from deep to superficial veins below the ankle, but from superficial to deep through the communicating vessels above.

Pathogenesis.—It is easy to understand the development of varicosities secondary to obstruction of the deep veins. Here they become dilated while acting in the capacity of collaterals. In iliofemoral thrombophlebitis the valves of the femoral vein may be permanently rendered incompetent by destruction and fibrosis. Extrinsic pressure at the iliofemoral junction may act in the same way. However, pressure within the abdomen due to pregnancy, tumors, and ascites will usually not result in varicosities if the valves are competent. Thus we see that the most important factors in the development of varicose veins is the condition of the valves. Incompetency of the valves may be present in the long saphenous (usually) or lesser saphenous, the perforating veins, or all of the superficial and communicating veins and may be due to: (1) Congenital absence. The external iliac and femoral veins proximal to the saphenous show no valves in about 33 per cent of all people. (2) Hereditary weakness in vein walls and valves which allows for dilation and incompetent valves from any cause which increases intralumenal pressure; namely, orthostatism, obesity, pregnancy, abdominal tumors, ascites, abdominal aneurysms. (3) Hereditary weakness which allows for phlebectasia due to decrease in extrinsic support as seen in thin, old, and emaciated men, in persons after prolonged bed rest, after plaster casts on the legs. From any of the aforementioned causes there results a series of pathological changes which consist of dilatation, elongation, tortuosity, fibrosis with variation in thickness, loss of elasticity due to fibrosis and stretching, incompetency of valves due to their atrophy. (4) Incompetency of valves in the communicating veins. Since the pressure in the deep veins is higher, blood flows into and stops in the saphenous.

If the saphenous vein is weak or diseased or if its valves are destroyed, it becomes enormously enlarged and tortuous because the blood gravitates down (in a reverse direction to the normal flow) when the patient stands. It is perhaps more correct to say that there is an inherent or congenital weakness in the varicosed vein which is aggravated by occupations which require long hours of standing. The column of blood extending from the right auricle to the ankle causes dilatation and sacculation of the vein, which may lead to complications, such as edema, ulcer, rupture of the vein, thrombophlebitis, eczema, and all manifestations of venous insufficiency with stasis.

Actually a reverse flow is rare, and if present at all it must occur in severe late cases with the patient standing still. In most cases there is probably stasis or very slow movement toward the heart which is not fast enough to carry away the capillary inflow. Active motion speeds up this re-

turn to some extent and elevation makes it normal. Blood pools to some degree in most people—soldiers standing at attention frequently faint. Experiments in which persons stand in a tub of water for a period of time show a rise in the level of the water due to swelling of the feet and lower legs. Patients with large capacious varicose veins may faint due to the enormous quantity of blood which may be trapped, thereby reducing blood volume. We have seen patients with varicose veins who presented symptoms of lightheadedness or sense of goneness after standing for several

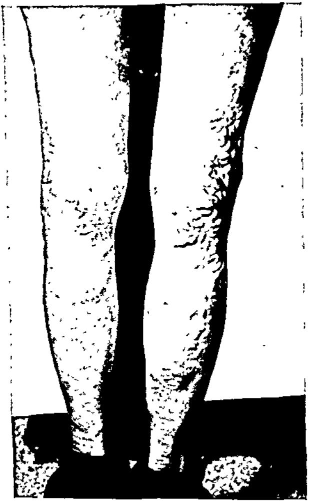

Fig. 186.—Varicose veins of both legs, with involvement of the greater and lesser saphenous.

hours. Walking or flexion of the legs helps, but unless they assume the recumbent position, collapse follows. Since the syndrome is transient, it must be due to temporary pooling with reduction of blood volume and vasoconstriction, and cardioacceleration follows with more blood pumped into the large varicosities then collapse due to aortic or carotid sinus reflexes. This same syndrome occurs occasionally in acute venous thrombosis.

Most observers have found an increase in venous pressure in varicose veins while patients are standing and normal pressure while recumbent. Some have found the reverse to be true and have felt that, as in arteriovenous fistula, there is an increase in blood volume in patients with large varicosities. When the patient lies down, an increase in circulating blood volume results, increasing venous pressures in the varicose veins which had normal pressures on standing. Arterial blood flow is unaffected in legs with varicose veins. But there is a higher incidence of arteriosclerosis of the leg arteries in men with varicose veins. This difference is not seen in women, who show a higher incidence of varicosities than men.

Pooling of blood leads to anoxia, and the increase in intravenous pressure plus anoxia contribute to the development of phlebosclerosis and intimal damage. Phlebitis and periphlebitis ensue with subsequent damage to the overlying skin, particularly over the most dependent portions of the involved veins.

Stasis with anoxia causes necrosis of tissue, and these tissues with their poor resistance may break down from the slightest injury, with the subsequent formation of a *varicose ulcer*. Healing will not take place because of *edema*, which prevents nutrient material and oxygen from reaching the tissue cells and waste products from being carried away. Stasis ulcer and postphlebitic ulcer are supposed to be special varieties of the lesion due to separate causes. Since the underlying cause is usually the same, the distinction is more academic than real. There is no doubt that ulcers do develop early in the presence of varicose veins, occasionally due to an underlying phlebitis and periphlebitis, resulting in cutaneous induration and ulcer. Really all injuries in the lower legs are slow to heal because a certain degree of stasis is present even in normal veins.

Competency of Veins.—Various tests are used to show the competency of veins. The Trendelenburg test simply occludes the long saphenous by a bandage with the patient recumbent. He then stands and the pressure is released. The incompetent veins fill from above down, with a sudden drop. The double Trendelenburg is used to determine the competency of the communicating vessels. With the above bandage in place, the saphenous vein will normally fill from below in about thirty seconds. If the communicating vessels are incompetent, this time is greatly reduced. Sometimes the saphenous vein is competent, the communicatnig vessels are not. In such instances the first Trendelenburg will be "negatve" and the double Trendelenburg will show that the saphenous fills no more rapidly even if the bandage is suddenly removed. Perhaps the most practical test for incompetent deep veins is the use of an Ace bandage or rubber stocking. Since patients with incompetent deep veins need the superficial veins as an aid in the return flow, any obstruction to them causes pain and swelling in the foot. Another simple manner to determine the competency of the deep veins is as follows: *A*

band is placed above the thigh just tight enough to occlude the superficial veins while the patient is standing. With the band in place, the patient is asked to lie down. If the deep veins are open, blood will leave the leg and the superficial veins will collapse. If not, they will remain distended. Another useful test is the one described by *Perthes*. A tourniquet is applied to the thigh tight enough to occlude the long saphenous but not the femoral. The patient is asked to walk rapidly. This causes the saphenous veins to fill with blood quickly. If the varices disappear rapidly on walking, the communicating veins are competent but the saphenous is incompetent. If the veins remain distended on walking, then both saphenous and communicating venous valves are inadequate. If, in addition, there is severe pain and the varices become larger and the foot and ankle swells, the deep veins are probably obstructed. By using this test at different levels up the leg, segmental thrombosis of the deep vein may be detected which might otherwise be missed due to blood circuiting around the obstruction. The Pratt test helps to locate the exact position of incompetent communicating veins. A tourniquet is placed around the thigh with the leg elevated tight enough to constrict the saphenous; an elastic bandage is then wrapped from the toes to the tourniquet. The patient stands, and as the bandage is unrolled, the bulging incompetent veins are apparent and a mark is made on the skin with an indelible pencil.

Treatment.—Patients with varicose veins demand treatment usually because of (1) general symptoms, (2) local complications, and (3) cosmetic reasons. Often patients will ask for instructions to prevent the formation of varicose veins since they know it to be a familial tendency. This is especially true in nurses, dentists, and others who know that orthostatic effects may hasten the development of phlebectasia. Obviously there is no prevention in those cases due to inherent weakness or congenital absence of venous valves. Avoidance of tight garters, long standing, and infections is desirable. Really the prevention of varicosities, except those secondary to obstruction, is a difficult problem.

Surgical intervention is the desirable form of treatment but when contraindications to surgery exist, other forms of treatment, even though palliative, may be instituted. Excision is contraindicated in arterial disease (thromboangiitis obliterans, arteriosclerosis, Raynaud's disease), in thrombophlebitis of the femoral vein, in cardiac decompensation, and when there is a great increase in intra-abdominal pressure from tumor or ascites; also in any severe infection in the leg (cellulitis or lymphangitis), advanced malignant disease, severe renal disease, uncontrolled diabetes, general infection until recovery is complete, active tuberculosis, and severe blood dyscrasia.

Most patients have some local complication of varicose veins and therefore the treatment of ulcer should be discussed along with the management of the varicosities.

The treatment of a varicose ulcer is to remove its cause: the stasis due to incompetent veins. Any measure directed against this will ultimately effect a cure. The idea is to send the blood back to the heart through the deep veins which are competent. This may be accomplished by elevation of the leg, elastic bandage, Unna's paste boots, or surgical excision of the useless veins. However, the surgeon will make sure that the deep veins are competent, that there is no intra-abdominal growth, and that no arterial disease is present before doing the latter. Once venous stasis is relieved, the ulcer will usually heal. The entire vein may be removed by subcutaneous tunneling. Most important is its interruption at the saphenous opening. This must be done by careful dissec-

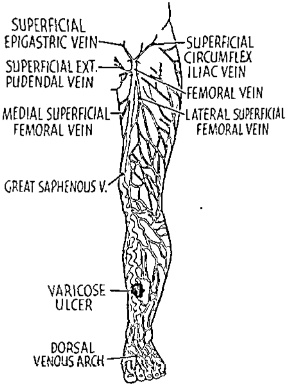

Fig. 187.—Diagram illustrating the great saphenous vein and its branches and a varicose ulcer in the usual location. This arrangement is by no means constant. Many variations occur. To break up the column of stagnant blood the saphenous vein must be divided in the saphenous opening, where it joins the femoral. To prevent recurrence, its five branches must also be divided The distal portion of the vein may be removed by "tunneling," or through small incisions along its course. It may be obliterated by the retrograde injection of sclerosing chemicals. However this method may be followed by deep thrombophlebitis. It is better to inject the sclerosing agent later after the effects of ligation have been determined.

tion of the long saphenous at its junction with the femoral in the saphenous opening, thereby interrupting the column of blood. In addition, the four branches are divided between ligatures, or excised. This procedure prevents the reformation of varicosities. Following the removal of the terminal section of the saphenous vein, the remaining varicosities are removed or stripped through short incisions. The Schede operation interrupts all branches by a circular incision down to the deep fascia which extends around the circumference of the leg. Percutaneous

ligation is useful in the treatment of small varicosities and may be used in conjunction with the above in severe cases. Recently much has been written about the injection method of treatment. Irritating solutions such as sodium morrhuate, 5 per cent, with benzyl alcohol, sodium ricinoleate, 3½ per cent, 50 per cent glucose, quinine, and urea hydrochloride have been used. This method is only temporary and is, in addition, painful and dangerous but will be successful in conjunction with ligation. The varicose ulcer is treated by applying a small rubber sponge on the gauze-covered ulcer and holding the sponge in place by an elastic bandage. This keeps the blood and serum out of the area until healing has occurred. Ointments and antiseptics have little value. The ulcer extends down to the deep fascia, which is usually not involved. Excision of the ulcer down to the fascia with subsequent skin graft may be necessary if extreme fibrosis is present.

Notes on Technique.—Extreme variations exist in the anatomical distribution of the tributaries of the saphena magna; therefore, each case demands wide exposure and careful search. All operations are done under local anesthesia. The best guide is the femoral artery—the vein lies medial. The incision is made just below and parallel with the inguinal ligament. The external or superficial pudendal artery is a guide to the saphenofemoral junction. Retrograde injection is not done because of the danger of (1) venospasm severe enough to cause reflux into deep veins through incompetent communicative veins, (2) arterial spasm which in arterial disease may finish the occlusion, producing gangrene, (3) sensitivity to the sclerosing agent. The lesser saphenous is ligated and divided as it enters the popliteal, if it is involved. Patients must be seen at six-month intervals—if new bulges occur, they should be removed or injected. Prognosis: usually good—not favorable in the obese or extremely thin and old.

Varicose veins are seen elsewhere in the body besides the legs. A few instances may be menitoned here. The usual cause is venous obstruction or arteriovenous fistula. *Prominent chest and arm veins* may be due to compression or partial obstruction of the subclavian between the clavicle and first rib anterior to the scalene tubercle. Decompression may be done Obstruction of the superior vena cava causes edema of the face and neck which is aggravated on recumbency and is better on arising. Collateral circulation is by way of the azygos. If the superficial veins of the thorax are occluded, venous pressure rises in the arms; if obstruction is close to the heart, inspiratory filling of neck veins may occur in congestive failure, constrictive pericarditis, and superior vena cava obstruction. The superior vena cava is rarely obstructed by thrombosis; it may be due to phlebitis, external compression due to tumors and cysts, mediastinitis, syphilitic, or tuberculous mediastinitis, aneurysms. Prognosis depends on the cause, Usually collaterals form. Thrombophlebitis rarely affects the axillary vein. It is seen following

severe bacteremia, surgical procedures, or intravenous injections by infected or hypertonic solutions. Sometimes a severe injury in or near the axilla may cause it. Occasionally it is seen in severe hemoconcentration from burns and other causes; also in polycythemia vera. *Esophageal varices* associated with Banti's syndrome, thrombosis of the coronary or portal vein, and atrophic cirrhosis may become very large and rupture, causing a fatal hemorrhage. Treatment of esophageal varices may be described under the following heads: (1) Direct attack includes obliteration by excision of the varices outside or inside the esophagus or by injection of sclerosing agents outside the esophagus or within the veins, or by their removal by resection of the lower esophagus and cardiac end of the stomach or the entire stomach. (2) Indirect attack attempts to decrease their size by lessening the amount of blood they carry. This is accomplished through splenic artery ligation or anastomosis between the portal and systemic venous circulations creating a shunt. Thus portal hypertension may be relieved by an Eck fistula, that is, portacaval anastomosis; also by anastomosis between the splenic vein and left renal vein after splenectomy but not nephrectomy and between the mesenterics and the vena cava or spermatic or ovarian veins (see Chapter 22).

Phlebothrombosis, Phlebitis, and Thrombophlebitis

Sometimes the deep veins are blocked also. It happens in phlebothrombosis and thrombophlebitis. Pathologically and clinically phlebothrombosis is probably the early quiet stage of thrombophlebitis. Etiologically it is the type of thrombophlebitis which occurs without previous inflammatory changes in the wall of a vein. Any foreign body in a vein incites a reaction or phlebitis, and a thrombus is no exception. Therefore a phlebothrombosis soon becomes a thrombophlebitis. The reason for the distinction is the increased probability in phlebothrombosis of a loose fragment from a propagating thrombus which is itself attached flimsily to the wall of the vein, breaking off and being carried to the lungs (See Chapter 5). This is not so apt to occur, in fact, rarely occurs in the later stage of thrombophlebitis when the thrombus is densely adherent. The entire process varies so much in different veins and from different causes that we must conclude that a phlebothrombosis occurs in some cases and remains silent for some time, whereas in others it incites so much reaction that it is a thrombophlebitis from the start—since this is true in all types of inflammation in all tissue, it is also true in veins. In other words, it is the causative factor and the resistance of the vein that determines the types. It should be stated, however, that the silent type is more apt to occur following surgery.

Thrombophlebitis has special names and implies a definite entity in various parts of the body. *Pylephlebitis* or pylethrombophlebitis (*pyle*, gate) are terms used to describe an inflammation and thrombosis with inflammation in the portal vein. Pylethrombosis is a thrombosis of the

portal vein. The inflammations usually follow suppurative diseases of the intestine, particularly appendicitis and diverticulitis. Pyelophlebitis (*pyelo*, a trough) is used to denote an inflammation of the renal vein or its branches.

The cause for *postoperative phlebothrombosis* is not definitely known and is probably a combination of causes which may be summarized under two heads: the increased ability of the blood to clot and the stasis with resultant anoxia of the circulating blood volume. The former has been attributed to (1) a decrease in heparin and an increase in antiheparin constituents because patients are "heparin resistant" for a variable period of time after surgery, (2) hyperprothrombinemia which is present after surgical operations (also after childbirth and coronary occlusion), (3) early decrease, then increased platelet count shortly after surgery, (4) increase in fibrinogen, (5) shift in albumin-globulin ratio in favor of globulin, (6) increase in blood viscosity which favors the agglutination of platelets which normally repel each other. The coagulation of blood is further favored by the postoperative leucocytosis and disintegration of platelets with an increase in thrombokinase. Dehydration and loss of plasma also shorten coagulation time. The slow circulation gives rise to stagnation with stagnant anoxemia. This is seen mostly in the legs in which the circulation normally is slower when immobile. Thus immobility, especially in the obese and those with varicose veins, is particularly conducive to intravenous clotting—in the former due to the obstructive factor which normally slows venous return and in the latter the large and tortuous channels which permit a certain amount of loitering within the varices. If the foregoing factors were all, then the disease should be preventable. But there must be still other causes as yet unknown. Certain it is that (1) phlebothrombosis may occur during the operation and therefore lengthy procedures are conducive, (2) stasis is not the only factor because pelvic operations are prone to be followed by phlebothrombosis in spite of the Trendelenburg position which keeps the veins of the legs empty (is it the local pelvic edema which interferes with venous return following surgery?), (3) phlebothrombosis is rarely seen after breast operations, thyroidectomy, and head operations (can this be explained on early movement, high systolic pressure, and restlessness, respectively?). Phlebitis *and* thrombophlebitis are probably seen most frequently clinically after two conditions: (1) after some acute infections disease, such as pneumonia or typhoid fever, and (2) after operations or abnormal obstetrical deliveries. The *causes* of phlebitis and thrombophlebitis are not definitely known. Among those which may operate are as follows: (1) Factors *outside the vein*, such as trauma during operations or obstetrical deliveries, traumatic injuries, inflammations produced by the streptococcus (cellulitis) or the staphylococcus (carbuncle of the upper lip), inflammation in suppurative appendicitis which may involve the portal vein (pylephlebitis), etc., giving rise to suppurative

thrombophlebitis; also in association with nonsuppurative lesions such as erythema nodosum, tuberculosis, and syphilis. (2) Factors *inside the vein*, such as toxins or infections in diphtheria, pneumonia, malaria, typhoid fever, etc., which produce an *inflammation of the intima*. (3) *Changes in the rate of blood flow*, producing stasis, as during long periods of bed rest (especially in old people) or in spinal anesthesia (long period of muscular inactivity), cardiac disease with failure, ischemia from arterial disease. Since venous flow is dependent in a great measure upon muscular action, there is stagnation due to continued immobility. This results in edema. A vasospasm occurs to counteract this loss of blood volume and the reduced blood pressure which accompanies it. This gives rise to an internal pooling of the blood and a shocklike syndrome. The night pains in the legs of individuals with arteriosclerosis are probably due to the above, with a resultant fall in blood pressure and decreased arterial flow. Thrombophlebitis is accompanied by a spasm of the affected vein and its branches peripheral to the lesion and by an arteriolar spasm as well. (4) *Changes in density of the blood*, as seen in starvation, dehydration, and burns (which produce *anhydremia*), polycythemia vera. (5) *Chemical changes in the blood* such as occur in anoxia, perhaps as a result of smoking, and in toxemias of pregnancy and burns; it may be produced by injection into the veins of a hypertonic solution (such as 50 per cent glucose), which irritates the intima (causes 2), destroys the red blood cells, and increases the density of the blood (cause 4). This may occur in long continuous intravenous drips of isotonic solutions, due to the irritation by the needle. It is also seen after intravenous injection of mercurial diuretics, penicillin, and other drugs. (6) Without any known cause a thrombophlebitis may develop. (7) In association with thromboangiitis obliterans by direct extension. (8) As recurrent idiopathic thrombophlebitis (phlebitis migrans). (9) Venospasm from any cause.

Post-Partum Thrombophlebitis.—After obstetrical deliveries thrombophlebitis with resultant edema is called "milk leg" or *phlegmasia alba dolens* (white and painful leg). It has been called "milk leg" because the early physicians thought it was connected in some way with the "coming in" of milk, since it usually occurred on the fourth or fifth day post partum. *Thrombophlebitis* in varicose veins is painful but not dangerous. It is also not accompanied with edema provided the deep channels are open. Those who inject sclerosing solutions in varicose veins really produce a chemical thrombophlebitis in an attempt to obliterate them. If the saphenous vein is not varicosed, the dangers of embolism are present, as is also the probability of postphlebitic edema.

Pathology.—In addition to the thrombosis and inflammatory reaction in the various coats of the venous wall, three varieties of thrombi have been described: (1) Red thrombi which are homogeneous and resemble post-mortem clots; this type is seen in local inflammation or injury to the vein; (2) white thrombus which consists of fibrin platelets

and leucocytes and usually is the older part; (3) *Mixed type which consists of white thrombus as the head and red thrombus as the tail.* The white thrombus tends to progress distally and may or may not occlude the vein. The red tail develops proximally very quickly and propagates as a result of increased blood coagulability. This tail may become adherent and fill the veins as a firm clot or it may be friable, flapping in the blood stream, giving rise to emboli. A thrombus which is more than *three days old rarely becomes detached. New propagating thrombi may* occur on the old and extend up to the juncture of a large tributary and stop, or others may form as a result of a secondary inflammatory reaction proximally.

The chief danger is the dislodgment of a thrombus which results in pulmonary embolism. Homans states that Kinney, Haynes, and Dexter have introduced a venous catheter into the pulmonary artery in a dog by way of the jugular vein and right heart. By inflation of a balloon at the tip of the catheter there is no change in pulse rate or respiratory rate, the systemic blood pressure, the right ventricular pressure, or the electrocardiogram. Only when infarction follows do signs and symptoms appear. If, however, emboli (lycopodium spores) are introduced into a lobe, acute symptoms follow. Apparently this reaction is due to a generalized constriction of the pulmonary arteriolar bed that is not limited to the one lobe. This does not explain sudden death which is apparently due to anoxemia unless the emboli occur in both lungs simultaneously.

Disturbance in Function.—Occlusion of the vein may be partial or complete and the results may be temporary or permanent.

Blood must come back by collateral circulation until the thrombus is recanalized or absorbed. It takes many weeks for this to take place, and sometimes it does not occur, in which event the return flow is entirely by collateral veins. At first there is marked edema about the ankle, which may disappear if the collaterals are adequate; if not, a permanent edema remains, because the hydrostatic pressure in the vein is much greater than the osmotic pull of the blood (Chapter 11). Some observers believe that part of the swelling is due to lymphedema (Homans) —that is, that it is the result of obstructed lymphatics as well as veins. Experimentally we can produce edema by ligating a long segment of *vein but not by one ligature. There may be a reflex arterial spasm which* at times is so great that gangrene may occur. Severe degrees of spasm are known as pseudoembolic phlebitis, phlegmasia caerulae dolens, or "blue phlebitis" of Gregoire.

Should the thrombophlebitis persist, a chronic type of inflammation results with acute episodes. Ultimately phlebosclerosis ensues with all the effects of obstruction to the venous return such as chronic edema, cyanosis, pruritis, eczema, ulcer, and varicose veins.

Symptoms.—Early symptoms are obscure; they consist of slight enlargement of the leg, local deep tenderness, increase in tone, and ir-

thrombophlebitis; also in association with nonsuppurative lesions such as erythema nodosum, tuberculosis, and syphilis. (2) Factors *inside the vein*, such as toxins or infections in diphtheria, pneumonia, malaria, typhoid fever, etc., which produce an *inflammation of the intima.* (3) *Changes in the rate of blood flow*, producing stasis, as during long periods of bed rest (especially in old people) or in spinal anesthesia (long period of muscular inactivity), cardiac disease with failure, ischemia from arterial disease. Since venous flow is dependent in a great measure upon muscular action, there is stagnation due to continued immobility. This results in edema. A vasospasm occurs to counteract this loss of blood volume and the reduced blood pressure which accompanies it. This gives rise to an internal pooling of the blood and a shocklike syndrome. The night pains in the legs of individuals with arteriosclerosis are probably due to the above, with a resultant fall in blood pressure and decreased arterial flow. Thrombophlebitis is accompanied by a spasm of the affected vein and its branches peripheral to the lesion and by an arteriolar spasm as well. (4) *Changes in density of the blood*, as seen in starvation, dehydration, and burns (which produce *anhydremia*), polycythemia vera. (5) *Chemical changes in the blood* such as occur in anoxia, perhaps as a result of smoking, and in toxemias of pregnancy and burns; it may be produced by injection into the veins of a hypertonic solution (such as 50 per cent glucose), which irritates the intima (causes 2), destroys the red blood cells, and increases the density of the blood (cause 4). This may occur in long continuous intravenous drips of isotonic solutions, due to the irritation by the needle. It is also seen after intravenous injection of mercurial diuretics, penicillin, and other drugs. (6) Without any known cause a thrombophlebitis may develop. (7) In association with thromboangiitis obliterans by direct extension. (8) As recurrent idiopathic thrombophlebitis (phlebitis migrans). (9) Venospasm from any cause.

Post-Partum Thrombophlebitis.—After obstetrical deliveries thrombophlebitis with resultant edema is called "milk leg" or *phlegmasia alba dolens* (white and painful leg). It has been called "milk leg" because the early physicians thought it was connected in some way with the "coming in" of milk, since it usually occurred on the fourth or fifth day post partum. *Thrombophlebitis* in varicose veins is painful but not dangerous. It is also not accompanied with edema provided the deep channels are open. Those who inject sclerosing solutions in varicose veins really produce a chemical thrombophlebitis in an attempt to obliterate them. If the saphenous vein is not varicosed, the dangers of embolism are present, as is also the probability of postphlebitic edema.

Pathology.—In addition to the thrombosis and inflammatory reaction in the various coats of the venous wall, three varieties of thrombi have been described: (1) Red thrombi which are homogeneous and resemble post-mortem clots; this type is seen in local inflammation or injury to the vein; (2) white thrombus which consists of fibrin platelets

are important in causing thrombophlebitis. Early mobilization is mandatory since normally most of the blood is in the veins. Judiciously used, this one procedure is perhaps the most important single preventive measure. Since phlebothrombosis is most common in the smaller veins of the leg, peroneal, anterior, and posterior tibial, the lower legs must be actively moved. Carefully planned anatomical incisions with meticulous closing permits early ambulation. The surgeon must keep the factors of wound healing in mind. One of these is rest to the part. If early ambulation prevents wound healing, thrombosis may occur at the wound site and give rise to emboli besides other complications such as dehiscence and local infection which also are conducive to thrombophlebitis. Therefore, early ambulation will not be possible in every case, but this should be our goal. If the patient cannot be trusted out of bed because of the condition of the wound, he should be encouraged to take deep breaths, exercise the arms and legs, turn frequently from side to side. The back rest is probably conducive to venous stasis. Since thrombi may form soon after the operation has begun, the anesthetist should be told far enough in advance to discontinue the anesthetic agent so that the patient may be moving soon after he leaves the surgery. Narcotics are used sparingly and immediately after their use; patients are told to move about and walk if possible. Indeed we are really "cruel" in our niggardly use of morphine. Nothing is more conducive to stasis than to keep a patient completely narcotized lying motionless, with slow shallow breathing. (4) Hemoconcentration, dehydration, hypoproteinemia, especially hypoalbuminemia, must be relieved by proper hydration and attention to protein balance. (5) Concentrated solutions are not used—isotonic intravenous therapy is desirable. In chest and other surgery the leg veins are used because of necessity. This is not continued after surgery. The "continuous "drip" has also been abandoned because of its irritation to the veins. *When normal blood flows through normal veins at a normal rate of speed, intravascular clotting does not occur.* (6) Particular attention to the foregoing routine is given obese people, those with varicose veins, and those with arterial disease of the extremities. (7) Prevention of vasospasm on the arterial and venous side may be accomplished by blocking the sympathetics by paravertebral injection of Novocain; also by the use of tetraethylammonium bromide or chloride. The drug is given intramuscularly in the dose of 20 mg. per kilogram. A 10 per cent solution—100 mg. per cubic centimeter is used and the maximal dose ranges from 1 to 1.2 Gm. Priscoline hydrochloride, 25 mg. every six hours, given by mouth, is easier to administer and equally effective. Vasodilation secured as outlined is probably a direct thwart to nature's protective vasoconstriction which increases end pressure and thus lateral pressure. Since most of the blood is in the veins, especially when the muscles in which they lie are immobile, and since on coughing or straining intravenous pressure is further increased

ritability of the calf muscles. Later there are spontaneous pain and pain on forced dorsiflexion of the foot (Homan's sign). Later still an inexplicable rise in pulse and temperature and some pleurisy pain are present. The less dangerous variety of thrombophlebitis begins with chill and an aching sensation down the leg, usually the left leg. Some say phlebitis in the left leg is due to the fact that the left iliac vein is crossed by the right common iliac artery (Homans denies this). There may be swelling of the ankle if thrombosis is extensive or complete. Sometimes there is redness over the femoral vein (inner side of thigh), and usually there is tenderness on palpation. One of the outstanding symptoms of venous thrombosis anywhere is *severe pain* which may be due to distention of the venous wall, arterial spasm, local anoxia, or combinations of these factors. The pain occurs in the leg in the hemorrhoidal veins (thrombosed hemorrhoids), in the lateral sinus in connection with mastoid disease, and especially in mesenteric venous thrombosis. In this latter condition the pain is as severe as in acute pancreatitis. One of the outstanding differential diagnostic features is the presence of blood in the stools. If the physician is on the lookout for phlebothrombosis, he will be less apt to miss it.

Prevention.—Postoperative phlebothrombosis and thrombophlebitis are preventable to a great degree but not entirely so. A glance at the probable causes will reveal the clue to prevention. These facts may be listed as follows: (1) The surgeon must constantly remind himself that veins are injured locally by surgical trauma. As a result of local inflammation and swelling due to this trauma, venous stasis is present distal to the area. This is particularly true in pelvic operations where the crucial veins lie which receive blood from the lower extremities. Once again the aphorism given in Chapter 1 reasserts itself—Handle the tissues with loving kindness and they with their veins will respond in like manner. (2) Septicemias and bacteremias should be controlled as much as possible by antibiotics and chemotherapeutic agents before surgery to avoid inflammation of the intima. Also these same agents may prevent postoperative infections. We must not rely too much on such agents. One of the most conspicuous examples of postoperative infections is that of cystitis following catheterization. This is particularly true in male patients. After such commonplace operations as hernia repair and hemorroidectomy, catheterization was a routine postoperative procedure which was entrusted to orderlies who were supposedly trained to catheterize aseptically and gently. A high incidence of cystitis resulted, with fever, dysuria, and prolonged bed rest. Here the bacteremia and stasis were conducive to thrombophlebitis and actually the complication was common following herniorrhaphy. Now our patients stand up beside the bed to void as soon as they are awake from their anesthetic—catheterization is unnecessary and thrombophlebitis extremely rare. (3) Changes in the rate of blood flow, producing stasis,

ensue. However, new and more competent collaterals quickly form to carry blood back to the heart. The patient must be careful about bruises, injuries, etc. for local immunity is decreased and infections or ulcers may occur. Intermittent external pressure over the entire extremity by elastic bandage should be used three or four times a day. This increases the fluid pressure in the tissue spaces until it is higher than the intravenous pressure, thus preventing further transudation and forcing fluid back into the veins and lymphatics. Ultimately this may cure the patient of the edema (postphlebitic). If the superficial veins are *competent, this method is very effective, for in addition to the foregoing,* adequate collaterals usually form.

2. The use of heparin, as outlined in Chapter 4, subcutaneously in Pitkin's menstruum or Depoheparin and/or Dicumarol and early ambulation. Their use has also been advocated after pulmonary embolism has occurred.

3. Vein ligation with or without thrombectomy. If early thrombectomy should be done—if late and not too difficult, thrombectomy may relieve the patient of many of *the late complications of thrombophlebitis.* Some even advocate bilateral femoral ligation prophylactically. In phlebothrombosis ligation of the superficial femoral does not prevent thrombosis in the deep, and ligation of one common femoral does not prevent thrombosis in the opposite vein; moreover, in iliofemoral thrombophlebitis both iliacs may have to be tied, and this has led to the ligation of the inferior vena cava below the renal veins. This seems to be a safe procedure in competent hands and collateral circulation is established by way of the *vertebrals, azygos, intercostals,* and superior vena cava. The procedure has even been suggested as an aid to the edema of long-standing thrombophlebitis by providing adequate collaterals. We have been opposed to vein ligation as a prophylactic or routine measure even after a single embolus. The dangers of vena caval ligation or bilateral iliac ligation are small but present. This adds another major operation to the patient's illness, with immobilization during and after the procedure—at least during the operation. Minor states of thrombophlebitis *with little tendency to postphlebitic complications* are converted into a true occlusive thrombophlebitis which is apt to be followed by sequelae. Most important is the fact that ligation per se does not guarantee against further thrombosis. In fact, a thrombus may form at the site of the ligature which may propagate. Large rapidly fatal emboli have been successfully removed (pulmonary embolectomy—Trendelenburg operation) in a few cases. This requires quick work with everything in readiness Thoracotomy is done and the clot removed from the pulmonary artery. For those patients who survive long enough for the procedure to be done, recovery is more likely without than with the operation usually.

4. Inactivation of regional *sympathetics* by injection of Novocain, tetraethylammonium bromide, Priscoline hydrochloride, or sympathetic

(Valsalva's experiment), the venous distention may dislodge a thrombus in early phlebothrombosis. With the drop in venous pressure during the next inspiration, the blood and thrombi are sucked and pushed up into the right heart, causing pulmonary embolism. To avoid this some have advocated pressure bandages to the legs before and after surgery. In my *Synopsis of Principles of Surgery*, under Prevention of Thrombophlebitis, I stated: "Perhaps the wisest treatment, once the condition occurs, is to cover the leg with an elastic bandage and permit gentle active (not passive) motion. This, with an anodyne to relieve pain, is all that is necessary." (8) Anticoagulants have been advocated by some—Dicumarol (3-3′-methylbis [4-hydroxycoumarin]) and heparin have been used. We do not consider this necessary as a routine postoperative procedure and the danger of hemorrhage must be considered together with the toxic effects of Dicumarol.

In a study made in 1936 of postoperative deaths in Indiana University Medical Center, for a period of five years, we found that in 5,133 so-called major operations, there were 155 deaths, a general mortality rate of about 3 per cent. Of this group, 53, or about 35 per cent of the deaths, were due to what we termed circulatory causes, an incidence of about 1 per cent. This we divided into cardiac, arterial, venous causes, and hematogenic shock.

Of the 53 circulatory deaths, 18 were due to venous thrombosis and embolism. In 1941, which was four years later, we again assembled our statistics. There were 8,979 major operations studied, and there were 162 deaths, a general mortality rate of 1.8 per cent. Of this group, 68, or 42 per cent of the deaths, were due to circulatory causes, an incidence of .75 per cent. Of the 68, only 10 were due to venous thrombosis and embolism.

Treatment.—As soon as thrombophlebitis is discovered, active treatment is designed to prevent pulmonary embolism and to ameliorate symptoms. The type of treatment depends somewhat on the veins involved: (1) superficial—the saphenous veins and tributaries, the median basilic and cephalic veins and tributaries, (2) muscular and deep veins of the calf, (3) popliteal and femoral veins, (4) iliofemoral veins, (5) axillary and subclavian. Also treatment will vary with the type of thrombophlebitis, depending on its cause and whether it is acute or chronic. In general the treatment which may be used in the acute variety is divided into four types:

1. Massage is strictly prohibited. The application of heat relaxes the venous and arteriolar spasm and hastens involution. After about two weeks the thrombus becomes adherent and is finally recanalized, or the vein is permanently occluded. If the patient also has varicose veins, they should be excised, for they are incompetent and do not really help the blood to return. If all return were interrupted, there would result an enormous swelling, due to edema, and ultimately, even gangrene would

into two main ducts—the right lymphatic duct (which may be double) empties into the right subclavian vein, and the thoracic duct empties into the left internal jugular or subclavian vein. Thus each main lymph channel empties into a large vein and the opening is guarded by a valve. The great veins at the root of the neck have a negative pressure and lymph is actually sucked into them during inspiration. Lymph is also propelled by muscular action and arterial pulsation as well as by external pressure. *The lymphatic system is therefore a closed one.* The lymphatics are almost as numerous as the blood capillaries and probably have a surface available for absorption even greater than the blood capillaries. There are valves in the tubular lymphatics just as in the veins, permitting flow only toward the neck, but no contractile element such as the Rouget cells. However, the endothelial cells are phagocytic. Fascial planes and spaces, mucocutaneous junctions, tendon sheaths, joints, and the pleural and peritoneal cavities are richly supplied with lymph vessels.

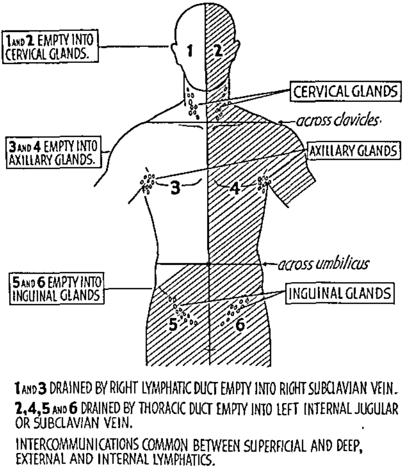

Fig. 188.—External lymphatics. Diagram illustrating roughly the lymph node basins and the areas they drain. The upper transverse line is drawn across the clavicles, the lower through the umbilicus, and the vertical through the midline of the body. Areas 1 and 2 include the head and neck; 3 and 4, the thorax, upper abdomen, and upper extremities; 5 and 6, the lower abdomen and lower extremities.

In general, the lymphatic vascularization of an organ is more abundant as its blood circulation is more active, and lymph vessels are usually more numerous than the blood vessels of the same region or organ. Anastomoses with neighboring lymph vessels are frequent. All lymph vessels except the terminal trunks empty into one or several nodes before they empty into the main ducts. There are exceptions to this occasionally,

ganglionectomy is certainly indicated in the presence of intense and continuous reflex arterial spasm. The first, second, third, and fourth lumbar ganglions are injected with 10 c.c. each of a 1 per cent solution of procaine hydrochloride. In addition, the second and third ganglia are injected with 10 c.c. each of monobromsoligenin (Bronisalizol) solution which inactivates the sympathetics for four to eight days. These procedures do relieve local symptoms, although heat and elevation will usually accomplish the same result. Inactivation of the sympathetics does not prevent extension or embolism; in fact, it may invite it, as shown by the large incidence of thrombophlebitis following sympathetic ganglionectomy.

Summary of Treatment.—We have felt that all facts considered, anticoagulant therapy with early ambulation is the treatment of choice. Rarely ligation may be indicated, but the indications are certainly not clear at present. In those who cannot get out of bed because of the condition of the wound (body casts, etc.), active motion in bed is desirable.

Complications and Sequelae of Thrombophlebitis.—(1) Chronic phlebosclerosis causes edema, superficial varicosities, and pain due to stasis and swelling. Edema may be the cause of ulceration because of interference with circulation and also because edema provides a good medium for bacterial growth. (2) Sudeck's atrophy of bone with muscular atrophy and vasomotor changes. (3) Suppuration in suppurative thrombophlebitis. (4) Gangrene if arterial disease is also present or follows.

Obstruction of large veins by new growth requires their resection. This is feasible and is usually not followed by great and persistent edema although there is usually some. Even portions of the vena cava have been resected below the renals with good results. Small areas of constriction due to fibrosis may be resected and anastomosed. Recently experimental anastomosis has been accomplished between the azygos vein and superior vena cava, azygos vein to atrium, and superior vena cava to atrium. These procedures may be useful in treatment of superior vena caval obstructions.

THE LYMPHATIC SYSTEM

The *lymphatic vessels* originate in the embryo as small buds from the endothelium of the right and left subclavian and iliac veins. From here they develop and finally form vessels over the entire body except in the brain and spinal cord, spleen, bone marrow, catilage, sclera, crystalline lens, and cornea, the epithelial tissues and placenta. There are two sets of peripheral lymphatics. The superficial or *reticular lymphatics* and blindly in the dermis and may be compared to a fine-mesh gauze over the entire body so close that even a hypodermic needle cannot miss them. These empty by communicating vessels into the deep or *tubular lymphatics*, which lie on the deep fascia and usually accompany the veins; in fact, all tissues and organs supplied with blood vessels also have lymph vessels except as previously noted. These in turn join the lymph glands or nodes, which lie along the course of the blood vessels, and are grouped into the cervical, the axillary, and the inguinal basins peripherally and the mesenteric, mediastinal, etc., internally. After leaving the nodes, the lymphatics come together

will be discussed in the chapters dealing with the different systems. Here we should consider general differences. Drinker and Warren state that in the dog the heart and lungs are drained by lymphatics which enter the right lymphatic duct and only the upper part of the left lung supplies lymph to the thoracic duct. Also, in at least half of the animals the right lymphatic duct carries chyle. The right lymphatic duct is not always present in man but when it exists it is very short (12 to 17 mm.) and is formed by the confluence of the right jugular trunk, the right subclavian trunk, and the right bronchomediastinal trunk. These three trunks may empty into the right innominate vein or two of them may unite and one remain separate. They carry lymph from the right side of the head and neck, right upper limb, right side of the trunk, including the upper part of the thoracic wall, right lung and pleura, right half of the heart and pericardium, right side of the diaphragm, and the upper surface of the liver.

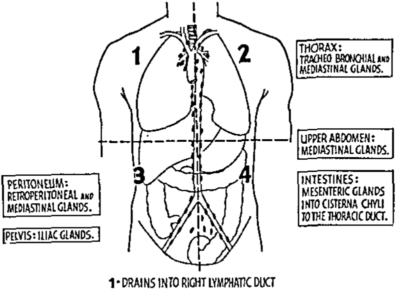

Fig. 189.—Internal lymphatics. Diagram illustrating internal lymph basins. A line is drawn longitudinally through the center of the body and transversely at the level of the attachment of the diaphragm. The superficial glands have connections with the deep basins. The right lymphatic duct gets lymph from the right lung, pericardium, and lower two-thirds of the left lung. The thoracic duct drains the left mediastinum, pericardium, and lung. Chyle is carried almost entirely by the thoracic duct in man but not in lower animals, where as much as 50 per cent is carried by the right lymphatic duct or ducts.

DISEASES OF THE LYMPHATIC VESSELS

Congenital Malformations.—Lymphatics may be absent in different regions. Sometimes it is the nodes that are missing; again lymphatic vessels are either absent or atretic. Such anomalies may produce very few symptoms if collaterals are ample, or there may be transient lymphedemas; more often they are perminent. The transient varieties usually are due to atresia or stenosis or absence of the right lymphatic duct producing chylothorax, the receptaculum chyli producing chylous ascites. Rarely the thoracic duct may be stenosed. The treatment for these types is repeated aspiration as indicated, replacement of lost protein by plasma transfusion, and high protein diet and low fat diet. We have recently had a 9-week-old baby with congenital chylothorax on the

and lymphatics may empty directly into the thoracic duct or the portal system without first passing through a lymph node. Also, efferent vessels of lymph nodes placed at a distance from the base of the neck may empty directly into the veins and the efferent lymph vessels of the thyroid gland may empty directly into the internal jugular vein or into the subclavian vein.

The wall of the thoracic duct differs from the large veins by having a better developed tunica media. The tunica adventitia merges into the surrounding loose connective tissue. It carries the tiny blood vessels which correspond to the vasa vasorum. When injured, the thoracic or right lymphatic duct should be ligated. Collaterals usually form to carry lymph back to the blood stream. Narrow, thin-walled lymphatics are often accompanied by small arteries and veins and capillaries; from these blood vessels encircle the lymph channel.

Physiology

The function of the lymphatics has been mentioned in the discussion of Starling's theory. Since their walls are extremely permeable and there is little or no hydrostatic pressure, they are easily affected by the pressure in the tissue spaces (intercellular spaces). The protein content of lymph is lower than that of blood plasma; therefore, the osmotic pressure is also lower, but the permeability of the lymph vessels enables them to absorb particulate matter (which is often taken up by phagocytic cells) and colloids (proteins). Hudack and McMaster have shown that dyes injected in the skin of the forearm appear in the lymphatics as high as the axilla within eight minutes—faster when gentle intermittent external pressure is applied.

Lymphocytic capillaries differ from blood capillaries in that the former have no gradient or permeation behaving as a semipermeable membrane. In all parts of the body the lymphatics carry away cells and solid substances from the tissues which cannot be absorbed by the blood capillaries. This is especially true of blood proteins which are being lost constantly in varying amounts all over the body except in the renal glomeruli, choroid plexuses, and capillaries of the ciliary body. Thus in all air-breathing animals solid substances and cells get back into the blood stream in spite of blood pressure. In fishes, lymph is forced into veins by contraction of lymph hearts placed on the lymph vessels before their entrance into veins. In frogs and birds the main lymph ducts are paired right and left vessels. If the capillaries lose large amounts of protein due to their increased permeability, in acute inflammations or venous obstructions, the osmotic pressure in the tissues will prevent reabsorption. However, the lymphatics, if open, will carry this protein back to the blood stream, especially if there is movement of the part, massage, or external pressure. Every movement of the body helps in this propulsion, even the pulsation of the arteries.

Lymph vessels in the intestinal villi are known as lacteals and empty finally into the thoracic duct. Their protein content will vary from 2 to 4.5 per cent and their fluid is milky (due to fat) after a meal. The blood capillaries of the liver and portal system are permeable to colloids and here leakage may easily occur if there are obstructions, or inflammations, or variations in protein content. The thoracic duct is therefore busy picking up this lost material through its terminals and returning it to the blood. The peritoneum has many lymph channels which penetrate the diaphragm and empty into the mediastinal glands—thence into the thoracic and right lymphatic ducts. The lymph system, then, is a closed channel whose chief purpose is to return colloid material to the blood, and the lymph is made up of colloids, crystalloids, lymphocytes, and macrophages absorbed from the tissue spaces. Lymph flows slowly (about 4 mm. a second) and only in one direction and that is centripetally; valves at the termination of the main ducts prevent reflux. The amount of lymph flowing through the thoracic duct is from 50 to 120 c.c. per hour.

Great variations from so called normals occur in the lymphatic system. Individual variations occur in different organs and regions. Many of these characteristics

otomy, and esophagectomy when the middle third of the esophagus is involved. Lymphorrhea usually stops with pressure, but chylorrhea does not as a rule. In fact, death may result from chylothorax or chylorrhea due to secondary infection, dehydration, and starvation. The white chyle is easily recognized when the thoracic duct is injured. The duct should be tied at both ends. Collaterals soon form and if the ends are placed in juxtaposition, recanalization may occur. Injuries to the right lymphatic duct are not so serious because lymph is easily carried by other routes and the loss of fluid is not severe.

Obstructions of Lymph Ducts

Obstructions of the lymph ducts may occur from (1) congenital anomalies, (2) trauma, (3) inflammations, (4) new growths, (5) obturations, (6) pressure from without, (7) miscellaneous and unknown causes.

As a result of obstruction to the lymph vessels from any cause there is *lymphangiectasis* or a dilatation of the terminal lymphatics with resultant lymphedema, and as a result of the latter a cellular reaction occurs in the tissues with fibrosis and often ulceration. The term elephantiasis has been used loosely to include any greatly swollen part. Originally it was used to designate the enormous swelling seen after obstruction of large lymph trunks in filariasis. It is not synonymous with lymphedema, since great swellings are often due to plasma edema and are seen in phlegmasia alba dolens and edema of the arm following radical mastectomy.

When the thoracic duct is obstructed within the thorax, a chylothorax may result; in the abdomen, chylous ascites and chyle may appear in the urine (chyluria). It is well known that simple ligation of the thoracic duct does not produce these entities. If the duct is cut and not ligated, chylothorax or chylous ascites results. In neoplasia it is perhaps obstruction and erosion which cause it. If large segments of these ducts are involved, collaterals do not form and chyle is lost. In this respect the thoracic duct behaves as large veins do in the lower and upper extremities (see Chapters 19 and 20).

Congenital Anomalies.—Congenital anomalies have been previously discussed.

Trauma.—Trauma may cause an obstruction by direct division of the ducts or by involvement in subsequent scar formation.

Inflammations.—Inflammations may occur after radical mastectomy, although the vein is also involved.

Acute Lymphangitis.—

Since lymphatics are so permeable, the great danger of a *spreading lymphangitis* is that of spread to adjacent and even distant tissues. An inflammation of the superficial set is known as *reticular lymphangitis* or *erysipelas.* Inflammation of the tubular lymphatics is

right side. Ninety thoracenteses were done over a period of nine weeks, drawing off a total of 12,711 c.c. of chyle. Fluoroscopic studies showed the chyle to be in the right upper posterior portion of the chest near the vertebral gutter and to be encapsulated. The child recovered without further surgery. The more permanent types include simple congenital lymphedema and lymphangiectasis affecting one member of the family and the hereditary type of Milroy's disease. We have recently seen a case of congenital lymphedema of one entire extremity associated with tuberous sclerosis or epiloia. Treatment consists of extensive removal of superficial fascia and suturing the skin to the muscle as described by Homans or using pedicle skin flaps of the thigh and "waltzing" them up onto the abdomen, thereby carrying lymph through these flaps to the lymph channels of the abdominal wall. (See Chapter 6.)

Fig 190.—Cystic hygroma of the neck in 10-month-old infant. Recovery followed surgical excision.

Congenital cysts and lymphangiomas will be considered later in this chapter.

Trauma.—Wounds of larger lymphatic trunks may produce lymphorrhea. This is seen after injuries to the axillary or inguinal basins. Injury to the thoracic duct may follow accidental wounds to the chest—bullet wounds or stab wounds. Sometimes it is injured during surgical procedures such as radical dissections of the neck for carcinoma, phrenic-

etc. Cardiac decompensation with edema leads to dilation of lymph vessels with valvular incompetence, thus increasing the edema already present.

Treatment.—The treatment of various types of lymphedema depends upon their cause. If an obstruction may be removed, the condition may be alleviated. Usually, however, treatment is directed toward reduction of edematous tissue, establishment of collaterals, and protection of the skin against pressure or trauma sores which develop on the slightest provocation.

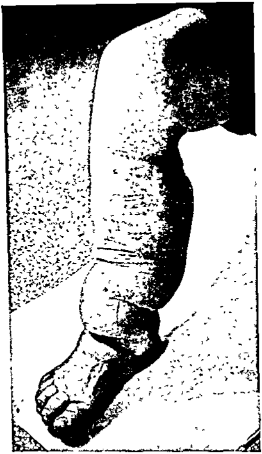

Fig. 191.—Elephantiasis due to chronic lymphedema. The patient was an obese man aged 38 years. The leg had been injured twenty-five years before. A chronic osteomyelitis developed, involving a large part of the tibia. There was extensive cellulitis, with subsequent fibrosis of the lymphatics. Due to the lowered tissue resistance, many superficial infections have developed. The serum protein of the blood was 8.4 gm. per 100 c.c.; that of the edematous fluid, 3.1 Gm. per 100 c.c.

Some of the methods used to develop collaterals have been reviewed in Chapter 6—these consist of rest, elevation, massage, elastic bandage. More radical forms of therapy are as follows: (1) Lymphangioplasty (Handley), which consists of burying long silk sutures in the edematous areas in the hope that new lymph channels would form. In this way a suture would be carried from the edematous areas of the left, for example,

a tubular lymphangitis (see Chapter 5). In three diseases the *tubular lymphatics* may have ulcers along their course: sporotrichosis, tularemia, and tuberculosis. *Acute lymphangitis* described in Chapter 4 as reticular (erysipelas) and tubular may recur periodically as acute inflammations or may become chronic. The tubular type is seen also in anthrax, chancroid (DuCrey's), glanders, syphilis, and even gas bacillus infection.

Chronic lymphangitis may follow an acute attack or it may be associated with venous obstruction as seen in "milk leg" due to thrombophlebitis and arm edema following radical mastectomy or injuries to the axilla. It may be associated with tuberculosis, trichophytosis, sporotrichosis, lymphopathia venereum (Chapter 7) and filariasis (see under Obturation).

New Growths.—When carcinoma cells grow into a lymphatic vessel (as in lymphatic permeation, discussed in Chapter 15), fibrosis occurs about the vessel, due to the irritation it engenders. This is known as *perilymphatic fibrosis* and it ultimately occludes the lymphatics, producing edema. The edematous extremities are easily infected and chronic ulcers form, increasing the edema.

Carcinoma may also obstruct lymphatics by secondary invasion from without.

Obturations.—Obturations may occur as a result of carcinomatous permeation or embolism. Rarer in the United States is the form caused by the *filaria sanguinis hominis* which are embryos living in the blood. The adult worm (Wuchereria [filaria] bancrofti) lives in the lymphatic system. During World War II this disease became common enough to take it out of the category of "tropical elephantiasis" and include it as a possibility in any enlarged part due to lymphedema. If all of the lymphatics of the leg are crippled, great swelling occurs. Local swellings may be due to enlarged lymph nodes, dilated lymph spaces (adenolymphocele), dilated lymph channels (lymphatic varices or lymphangiectasis); hydrocele, chylothorax, chylous ascites, chyluria may occur due to invasion of the genitourinary tract and invasion of the mesentery. Obturation may also occur due to the blood fluke, to Bilharzia hematobia, and to thrombosis of the left subclavian vein where the thoracic duct empties.

Pressure.—Pressure from without on the lymphatics causing obstruction may be due to new growths, enlarged lymph nodes due to tuberculosis, aneurysm, large goiter, particularly intrathoracic.

Idiopathic and Miscellaneous Causes.—Many types of lymphatic obstruction producing lymph stasis and thus lymphedema are idiopathic. In this group is *lymphedema praecox* (Allen and associates) which occurs without known cause in girls between 9 and 25 years of age; also *elephantiasis nostras* in the same group and probably the same entity. Also the various causes may act simultaneously—thus carcinoma by obturation and compression, inflammation by stenosis due to fibrosis and edema,

dium. (5) Cellular or endothelial lymphangioma is a neoplasm arising in the endothelium of lymph vessels. Like the hemangioendotheliomas, it may arise in any organ or tissue, and since blood vessels have small lymphatics about them, a perithelioma arising on perivascular lymphatics has been described. Metastases are rare but local recurrences are frequent.

Treatment.—The treatment varies in the different types. Capillary lymphangioma may be excised or treated with x-ray or carbon dioxide snow. Cavernous types are best excised if feasible. The incidence of postoperative infection is great and recurrence is common. X-ray and radium may be used. Cystic hygroma should be excised. X-ray is of no value and excision should be done before these cysts become secondarily

Fig. 192.—Lymphangioma of the tongue.

infected because this complication may be fatal. Sometimes the endothelial sac is so intimately adherent to the large vessels of the neck that portions of the wall must be left. These areas may be cauterized with phenol and then neutralized with alcohol. The diffuse systemic type is best treated with Kondoleon type operation, but this is often valueless. Postoperative infection is common and amputation may be necessary. Endotheliomas should be excised if possible and then treated with x-rays. If excision is not feasible, x-ray treatment alone causes prompt disappearance of the growth which may, however, soon return.

LYMPH NODES

Lymphatic nodes develop from lymphatic sacs which separate into groups of connected lymphatics, forming the node and filtering the lymph from the area previously drained by the sacs. These areas are usually deep basins such as the deep iliac, jugular,

up to the abdomen. This is not often successful. (2) Kondoleon operation, which consists of bilateral incisions in stages in the leg, extending throughout its length, turning up skin flaps, excising subcutaneous tissue and muscular aponeurosis, and replacing skin. This has not been very successful. The muscle has no lymph and drainage is not restored. (3) Homan's operation is similar to the Kondoleon but is restricted to dissections below the knee. (See Chapter 6.)

Obstructions to the Thoracic Duct

Obstructions to the thoracic duct deserves special mention because of its many causes and its consequences. Many causes have already been mentioned and are included here for completeness. They are (1) obstructions due to outside pressure such as mediastinal tumors, enlarged mediastinal nodes, greatly enlarged heart, aneurysm, intrathoracic goiter, mediastinitis (syphilitic, or tuberculous); (2) involvement of the duct by carcinomatous extension from the lung or nodes, tuberculous processes; (3) obturation by accidental ligature in surgery, filariasis, bilharziasis, neoplastic cells from the abdomen, thrombosis or occlusion of subclavian vein at the duct's entrance. When obstructed, chylothorax, chylous ascites, and even chyluria may ensue.

Lymphangioma

Lymphangiomas, like hemangiomas, may be due to congenital anomalies or may be new growths; a third group is due to lymphatic obstruction, congenital or acquired: (1) The simple *capillary lymphangioma* or lymphatic nevus may be flat or slightly elevated and is recognized by a different color from the surrounding skin, being pink, and by a slight thickening usually following the course of superficial nerves. (2) The *cavernous type* involves the skin and subcutaneous tissue and is composed of dilated and saccular lymph vessels whose endothelium may be greatly thickened; often hemangiomas are associated. Cavernous lymphangioma are seen about the head and neck, the genitals, and mesentery. Frequently they involve the lip or tongue, producing macrocheilia (large lip), macroglossia (large tongue), macromala (large cheeks). When cavernous lymphangioma involves the mesentery, it is known as chylangioma. (3) The cystic type, *cystic hygroma,* is a congenital dilatation of lymph sacs and usually occurs in the neck. We have also removed the growths from the axilla, inguinal region, and retroperitoneal space. They are occasionally seen in the pelvis, thoracic wall, and sacral area. This may be in one or many subdivided compartments. It may be intimately connected with the large vessels and nerves. It transilluminates light and thereby differs from bronchogenic cysts. (4) The diffuse systemic variety involves an entire extremity, producing enormous swelling due to lymphangiectasis; all lymphangiomas are easily infected and this type is particularly prone to be, for lymph is an excellent culture me-

there will be no swelling and an early, perhaps fatal, bacteriemia. The lymph nodes usually stem the tide and then return to normal after the infection is subdued. Occasionally the node breaks down as a result of the infection, and suppuration, with abscess formation, occurs. This requires incision and drainage. There are many *causes for the enlargement of the lymph nodes.* They may be classified as follows:

Infections and Toxemias.—

Acute Lymphadenitis.—Acute lymphadenitis is usually local, with involvement of the particular group of nodes in the area into which the infection drains: the cervical nodes in tonsillitis, the axillary nodes in infections of the hand, the inguinal nodes in infections of the foot, etc. The causative organisms are usually streptococci or staphylococci or both. A section of the node reveals the picture of an acute inflammation, with many polymorphonuclears and macrophages, much vascularity, and swelling. Lymph nodes are a valuable defense mechanism and usually annihilate the invading organism. Sometimes they break down and suppurate, or in long-drawn-out infections they may become fibrotic. Rarely, an infection (streptococcic) may cause no enlargement, in which event bacteriemia results quickly. In acute lymphadenitis the nodes are large and painful (and if near the skin, there is redness and tenderness), with fever and leucocytosis; nodes are also enlarged in tularemia.

Tuberculous Lymphadenitis.—The abscess, instead of being hot and tender, is cold and not painful (cold abscess). The nodes become matted together and undergo liquefaction. Usually the cervical nodes are involved. Children are usually affected and the bovine strain is probably responsible. Formerly extensive excision of these nodes was practiced. This is justifiable if they are the primary and only focus. Since the infection is rarely limited to the nodes, ultraviolet light, x-ray, and sunshine are now used instead of surgery. In most instances the nodes will recede, and recovery is the rule. If a cold abscess forms and breaks through the skin, a chronic sinus results. It will drain until all tuberculous tissue is removed, or until all necrotic tissue is extruded. Histologically, the primary type resembles a nonspecific infection. The adult type shows typical tubercle formation, with caseation.

Syphilitic Lymphadenitis.—The nodes are discrete, usually small, and painless. They do not suppurate or liquefy. With all the other evidences of syphilis, it is not a difficult diagnosis to make. They are seen in primary syphilis in the inguinal region, while in secondary syphilis all of the lymph nodes may be involved. Rarely, tertiary syphilis causes a gummatous formation. The treatment consists of antisyphilitic therapy.

Serum Sickness.—Serum sickness comes on eight or ten days after the giving of horse serum to sensitized patients. It will cause temporary swelling in the nodes, which recedes after forty-eight hours.

etc. Later the peripheral nodes are formed along the course of the lymphatics. The lymph sac is converted into a node by the ingrowth of surrounding mesenchyme, forming bars or partitions. The lymphatic sinuses arise in part as blind anastomosing spaces made from these mesenchymal cells; later these sinuses join with the endothelial-lined afferent and efferent vessels. Some lymphatic sacs remain as such; namely, cysterna chyli and jugular sacs.

The term regional lymph node is used to mean the node or nodes which receive the lymph of the area or organ in that region. This is, to some extent, a misnomer because the nodes may receive lymph from other areas and may not receive all the lymph of the area involved. In general, however, the well-known node basins outlined in the accompanying figures do receive lymph from the areas shown and in that sense are regional nodes.

Lymph nodes do not regenerate well after injury. Instead, they heal by scar tissue formation. As the individual ages, the number of lymph nodes diminishes; at least they diminish in size and become fibrotic, undergoing involutional change. Is this one of the reasons for the slow metastasis of cancer in the aged? Perhaps, but one finds involved nodes in large numbers in advanced cancer at any age.

Hemal nodes may be considered as filters of lymphatic tissue, situated in the course of blood vessels, with function and structures similar to the spleen. They do not occur in man but are found in lower animals, especially ruminants. Their sinuses contain blood and there is no lymph connection.

Lymph node is a better term than lymph gland, although the node has a glandular function. Since other glands exist in the neck particularly, metastasis to glands may be mistaken to mean parotid, submaxillary, or even thyroid gland.

Lymph glands or *nodes* are first seen in the maxillary, iliac, and axillary regions but probably arise from separate islands of tissue. They are small kidney-shaped organs which are found in groups. The lymph vessels enter at the cortex (afferent) and leave the medulla (efferent). When the lymph enters the cortex, it flows freely through a meshwork of reticular tissue which is a *syncytium* of argyrophilic cells. These cells (macrophages) are an important part of the reticuloendothelial system. Whenever bacteria or other foreign bodies are carried into lymph glands, they are engulfed by them. Also, in these meshes are found lymphocytes. The whole mass is penetrated by tortuous lymphatic spaces or sinuses. Their walls are not continuous. The valves of the afferent lymphatics direct the flow toward the node, and the valves of the efferent vessels direct the flow away from the node; that is, the flow is always toward the blood stream. Since the lymph nodes are made up chiefly of lymphocytes and phagocytes, their chief function is dependent on these cells. The former may give rise to fibroblasts, macrophages, polyblasts, and epithelioid cells. In tuberculosis, the latter cells engulf foreign bodies. In addition to the formation of lymphocytes, the lymph nodes act as a filter or sieve, detoxifying, elaborate antibodies (hemolysins and agglutinins), and have bacteriostatic powers. Lymphoid tissue such as occurs in lymph nodes is found in the nasopharynx, intestinal tract, liver, and spleen also.

Infections in Lymph Nodes

Lymph nodes may be termed the "second line of defense" guarding the blood stream. If an infection involves the tubular lymphatics, it will be carried to the lymph glands, causing a tender swelling. This is an excellent defense. If massage or pressure is exerted on an extremity, there will be an increased lymph flow, which will cause a temporary enlargement of the neighboring lymph glands. Lymph node enlargements are due to many causes. The nodes may be fightinng an infection. If the infection is so severe that it goes right through the lymph nodes,

action to this invasion; in others fibrosis occurs. An enlarged node in the vicinity of a carcinoma may not be carcinomatous but inflammatory. This is especially true in late ulcerating carcinoma anywhere in the body, for such carcinomas are usually secondarily infected. This infection occurs earlier in the mouth and in gastrointestinal carcinomas than elsewhere. Large nodes in the neck are difficult to diagnose without biopsy, but this should be withheld until a careful search has been made for a hidden carcinoma of the nasopharynx. Since drainage of lymph into "nodes of the first echelon" may be capricious, occasionally a distant node precedes a proximal one in being invaded. Carcinomatous nodes are usually involved in sequence; therefore, in removing them they should be excised en masse so that lymphatics laden with malignant cells will not be cut across. Some sarcomas metastasize to lymph nodes either directly or indirectly through involvement of adjacent blood vessels.

The treatment of carcinomatous and sarcomatous nodes depends on the extent of the primary growth and the degree of involvement of nodes. In carcinoma of the lower lip, for example, excision of the primary growth and the submental submaxillary nodes is justifiable because these are regional and their early and complete excision may be curative. If, however, distant metastases, which in this instance are rare, are present, this procedure would not be justifiable. X-ray and radium are widely used, the former more than the latter, in addition to surgery or alone.

Malignant Lymphoma.—Malignant lymphoma constitutes a group of *lymphoblastic diseases* of unknown etiology that are usually fatal. A simple classification is as follows: (1) Malignant hyperplasia of lymphoid cells, general or involving a group of lymph nodes; (2) The presence of increased numbers of lymphocytes, usually young or immature lymphocytes in the peripheral blood; (3) Malignant proliferation of lymphoid cells and, in addition, invasion of surrounding tissue; lymphatic leucemia, aleucemic form—factor (1); lymphatic leucemia—factors (1) and (2); lymphosarcoma—factors (1) and (3) lympholeucosarcoma or leucosarcoma (acute lymphatic leucemia)—factors (1), (2), and (3).

The lymphoid cells in the different types look alike and are indistinguishable to most pathologists. The gross appearance of lymph nodes likewise is not characteristic. Hodgkin's disease probably belongs in a class by itself because of its varied behavior but is included here in the lymphoblastomas.

Lymphatic Leucemia.—All lymph glands and lymphoid tissues are enlarged and there is a great increase in the number of lymphocytes: small mononuclears in the chronic and large mononuclears in the acute type. The white blood cells will sometimes reach 150,000 to 200,000 per cubic millimeter. Blood platelets are reduced, causing a tendency to hemorrhage. It is a disease of the bone marrow as well as of the lymph

Lymphogranuloma Inguinale.—Lymphogranuloma inguinale is a disease caused by a filtrable virus (see Chapter 7). The lymph nodes break down, forming draining sinuses. The treatment is the Frei antigen, or excision, penicillin, or streptomycin.

Miscellaneous causes are: yaws, virus diseases, infections, mononucleosis, Ducrey bacillus. Virus infections usually cause a swelling of the lymph nodes and lymphoid tissue in the intestines and elsewhere. This may explain the frequency of appendicitis in colds, influenza, measles, and poliomyelitis. Blood counts are normal or low but rise with appendicitis.

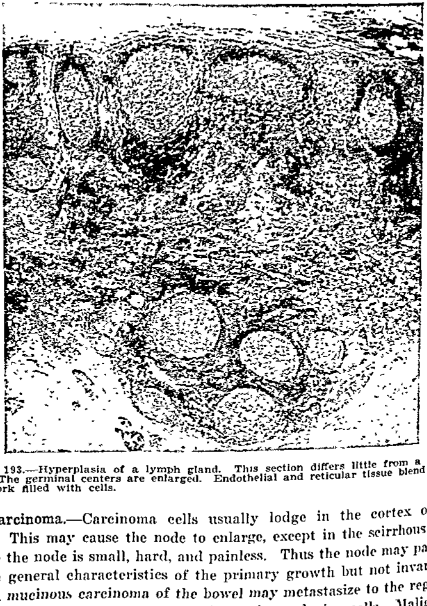

Fig. 193.—Hyperplasia of a lymph gland. This section differs little from a normal node. The germinal centers are enlarged. Endothelial and reticular tissue blend into a meshwork filled with cells.

Carcinoma.—Carcinoma cells usually lodge in the cortex of the node. This may cause the node to enlarge, except in the scirrhous type, where the node is small, hard, and painless. Thus the node may partake of the general characteristics of the primary growth but not invariably so. *A mucinous carcinoma of the bowel may* metastasize to the regional nodes which may or may not contain mucin-producing cells. Malignant cells may grow in the cortex of the node and permeate the deeper sinuses and thus involve other nodes. Some nodes show an inflammatory re-

creased. The treatment is x-ray, which may arrest but does not cure the disease. Nitrogen mustard, methyl bis (2 chloroethyl) amine hydrochloride may help ameliorate symptoms.

Lymphosarcoma.—Lymphosarcoma is a malignancy of the lymph glands. The glands are enlarged, painless, and discrete. X-ray causes a prompt diminution in size and is therefore diagnostic but not curative. The microscopic picture presents a monotonous replacement of the node by malignant mononuclear cells. There is an associated anemia.

Chloroma.—In addition to the conditions which have been outlined, a disease known as chloroma, lying midway between lymphoblastomas and new growths, is occasionally seen. Lymphoid tissue everywhere is involved and has a greenish appearance.

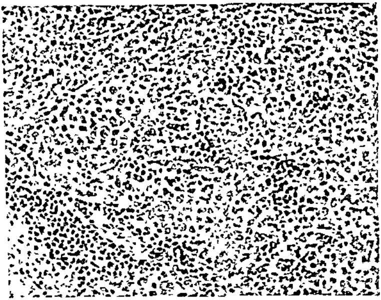

Fig. 195.—Aleucemic reticulocytoma. Lymph gland. showing enlarged reticulo-endothelial cells.

Summary.—Lymph nodes, then, may enlarge physiologically, through simple hypertrophy and hyperplasia, to meet an increasing demand for lymphocytes; or pathologically, from infections, new growths, or causes as yet unknown. A pathological enlargement of the lymph nodes constitutes a *system disease*—that is, a disease apparently limited to the lymph nodes, the bone marrow, and, in the leucemias, to lymphoid tissue. Diagnosis in every case is made by blood counts, sternal puncture for bone marrow study, and biopsy. The bone marrow and lymph nodes are the manufacturing plants and storehouses for cells entering the peripheral blood. If they contain many abnormal or unusual cells, then the peripheral blood will ultimately have them in most cases; therefore, the advisability for bone marrow and lymph node study. Diagnosis is always difficult, especially in children. Although the malignant lympho-

nodes. The histological picture in the nodes is one of hyperplasia of the germinal centers, with masses of lymphocytes scattered everywhere among the fine reticulum. X-ray therapy will help diminish the size of the nodes but will not arrest the disease. Recently folic acid antagonists have been used with some slight improvement. The principal drugs in this group are aminopterin (4-aminopteryol-glutamic acid) and aminoanfol (4-aminopteryol-aspartic acid).

Aleucemic Leucemia.—Aleucemic leucemia is a lymphoblastoma of bone marrow without dissemination. The blood count is low. In taking a sample of the bone marrow, one finds a typical picture of abnormal cells. This may be a forerunner of lymphatic leucemia.

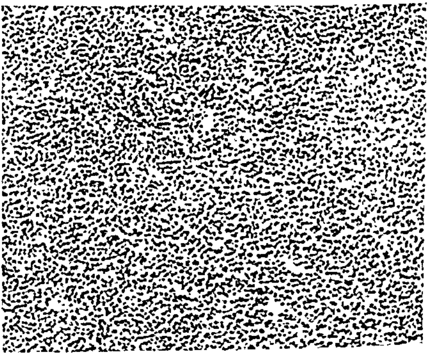

Fig. 194.—Lymphosarcoma. There is a monotonous field of abnormal lymphocytes.

Hodgkin's Disease, Lymphadenoma, or Lymphogranuloma.—The glands may be enlarged over the entire body or may be more pronounced in one group, as in the neck. They are hard and discrete. A relapsing type of fever is often seen (Pel-Ebstein). The microscopic picture of the gland is not always characteristic, but the Dorothy Reed cell (a special type of macrophage) and the increase in eosinophils are said to be characteristic. This picture varies from that of a nonspecific lymphadenitis in the early stage to lymphosarcoma in the late stages. There is itching and dermatitis, with pigmentation. Since in addition to the skin the liver, lungs, kidneys, bones, and central nervous system may be involved, some have classified it as a malignant new growth, Hodgkin's sarcoma, spreading by metastasis. The blood platelets are usually in-

mas are almost invariably fatal, physicians must continue their classification and study with the hope that an ultimate solution of the problem will appear.

TABLE XV

TUMOR AND TUMORLIKE CONDITIONS OF THE LYMPHOCYTE, THE MYELOCYTE, THE ERYTHROCYTE, AND THE RETICULUM CELL

(Modified from Collander [Lymphatic Tumor Division of American Registry of Pathology, Army Med. Museum]: Am. J. Path., 1934.)

ADULT CELL TYPE	LYMPHOCYTE	MYELOGENOUS		RETICULUM CELL	
		GRANULOCYTES	RED BLOOD CORPUSCLES	RETICULOCYTE MONOCYTE	HODGKIN'S DISEASE
Reactions to stimulation	*"Lymphoma"; lymphocytosis	Leucocytosis	Symptomatic polycythemia	Gaucher's disease; Niemann-Pick disease	
Proliferation of neoplastic type	Leucemic lymphocytoma (lymphatic leucemia): (1) chronic; (2) acute	Leucemic myelocytoma (myeloid leucemia): (1) chronic; (2) acute	(1) Polycythemia vera; (2) leucemic erythrocytoma	Leucemic reticulocytoma (monocytic leucemia)	
Not in peripheral blood	Aleucemic lymphocytoma (aleucemic leucemia) (lymphatic pseudoleucemia): (1) diffuse; (2) nodular	Aleucemic myelocytoma: (1) single; (2) multiple (multiple myeloma)	†Aleucemic erythrocytoma	Aleucemic reticulocytoma (aleucemic reticulosis)	Generalized
Malignant tumors	Lymphosarcoma: (1) without leucemic blood; (2) lymphosarcoma with leucemic blood	Myelosarcoma: (1) taleucemic; (2) leucemic (myelocytic leucosarcoma and myeloid chloroma)	Erythrosarcoma: (1) taleucemic; (2) leucemic	Reticulum cell sarcoma	Sarcomatous

*Applied by some to local hyperplasia due to inflammation.
†Not observed in Registry material.

Chapter 18

THE NERVOUS SYSTEM

The nervous system is almost entirely ectodermal in origin and its basis is the *neural plate* which folds into a *neural groove* bounded on each side by a *neural fold*. Soon the folds meet forming the *neural tube*. The cranial and spinal ganglia are derived from the neural or ganglionic crest which lies along the line of junction of the neural plate with the general ectoderm. The neural tube does not give rise to the nerve cells and fibers of the olfactory epithelium and certain cranial ganglia that arise in part from spinal epidermal thickenings called *placodes*.

From the neural tube cells come the neuroblasts which give rise to the nerve cells and the spongioblasts which give rise to the ependymal and neuroglia cells (astrocytes) which make up the supporting tissue of the nervous system. Some spongioblasts are migratory and differentiate into oligodengroglia as well as astrocytes. *Microglia* is usually listed as belonging to the neuroglia. These are ameboid phagocytes and probably originate from mesodermal cells and should be called *mesoglia* (Arey).

The supporting cells of the cerebrospinal ganglia at first seem to be a syncytium in which are neuroblasts. The interstitial elements differentiate into cells which invest the ganglion, *capsule cells,* and those which envelop the axons, *sheath* cells.

The neurilemma sheath (Schwann) is composed of cells from two sources; namely, tissue of the early neural crest and the neural tube by way of the ventral roots. At first the sheath cells enclose bundles of nerve fibers; later, as the cells multiply, the bundles are separated and each fiber has its neurilemma.

The *myelin sheath* begins to appear about the fifth month and is derived from the neurilemma or the axis cylinder or both. In the central nervous system there are no distinct sheaths of Schwann but there are scattered sheath cells which are apparently unable to cause regeneration after injury. See Chapter 3.

Vierordt estimated the number of nerve fibers in the spinal nerve trunks at over 800,000 and the number of fibers in the cranial nerves from the third to the twelfth inclusive at 200,000. Arl estimates the number of fibers in the right and left optic nerves of the human adult at about 2,600,000. This gives a total of 3,600,000 fibers without the olfactory nerves. Since many of these nerve fibers branch as they extend peripherally, this number is only a small fraction of the total, just as the large branches of a tree are only a small part of the total number of twigs.

The *fifth*, or *trigeminal, nerve* is the greatest sensory nerve of the face, having as its three divisions the (1) ophthalmic, (2) maxillary, and (3) mandibular nerves, all of which have their nuclei in the gasserian ganglion. It is of clinical importance chiefly because of the pain that may occur from irritation of this nerve. Such a state is known as *tic douloureux*. The motor part of the fifth nerve is distributed chiefly to the muscles of mastication.

The *sixth*, or *abducens, nerve* supplies the external rectus of the eye and when it is divided or injured the eyeball rotates to the inner side and produces an *internal squint*.

The *seventh*, or *facial, nerve* is the chief motor nerve of the face and supplies the muscles of expression. When it is injured or diseased so that its function is impaired, the muscles on that side of the face will be paralyzed. The paralysis will be complete if the injury is peripheral and partial if the injury is central because of cross innervation. If the patient is asked to smile, his cheek and mouth will be drawn to the opposite side. This condition is known as *Bell's palsy*.

The sensory portion of the seventh nerve is the *nervus intermedius*, the peripheral fibers of which represent parts of the greater superficial petrosal nerve and the chorda tympani branch of the facial; the central fibers form the nervus intermedium. The cells of these fibers lie in the ganglion genicula of the facial nerve. The nervus intermedius contains afferent sensory and vasodilator (parasympathetic) fibers. The taste buds and mucous membrane of the anterior two-thirds of the tongue are innervated by the chorda tympani, and the mucous membrane of the soft palate and posterior part of the nose send impulses by way of the superior petrosal nerve and the sphenopalatine ganglion. Secretory and vasodilator fibers to the lachrymal gland and palate (superior petrosal nerve) and the submaxillary and sublingual glands (chorda tympani) form the efferent components of these nerves.

The *eighth*, or *acoustic, nerve* is the nerve of hearing. Any disease or injury to this nerve will produce an interference with the functions of hearing or of equilibrium (semicircular canals of the middle ear) so that dizziness may be complained of. *Dizziness*, or *vertigo*, denotes loss of equilibrium manifested as a sense of rotation with reference to surrounding objects in space. The vestibular portion of the membranous labyrinth is the end organ responsible for impulses controlling orientation in space or equilibrium. The causes of this distressing symptom include uneven motion (car and sea sickness); cardiac, renal, vascular diseases, pernicious and severe secondary anemia (produce hyperemia and anemia of labyrinth); leucemia and purpura (produce hemorrhage into labyrinth); toxic vertigo caused by alcohol, tobacco, quinine, salicylates; nitrogen embolism (caisson disease, aviator's), Ménièr's symptom complex (allergic); ocular vertigo; lesions of the cerebellum or cerebellopontine angle such as tumors, cysts, abscesses, vascular anomalies which press

THE CRANIAL NERVES

The senses of man are (1) sight—light, form, and color; (2) taste; (3) touch—deformation of the skin, tickle and vibration sense, and the deep sensibility of muscle; (4) temperature—heat and cold; (5) smell; (6) proprioceptive stimuli from the muscles, tendons, and joints, informing the organism of location in space; (7) changes in position in space through the functional activity of the semicircular canals, the utricle, and the saccule; (8) hearing; (9) pain from skin, muscle and blood vessels; (10) visceroceptive stimuli of which persons are usually unconscious but which probably affect vasomotor, respiratory, and cardiac changes reflexly; for example, the inhibition of respiration from distention of the lungs.

The nerves of special senses are twelve in number (called the cranial nerves) and may be listed as follows:

The *first*, or *olfactory, nerve* is the nerve conveying the sense of smell and has its cells in the anterior lobe of the brain. In new growths in this portion of the brain *anosmia* may occur, providing a useful sign to the neurologist in diagnosis.

The *second*, or *optic, nerve* is the nerve of vision. Its importance from a diagnostic standpoint is that in any increase in intracranial pressure of long standing, the venous return and the cerebrospinal fluid circulation are impeded. This results in edema and there will be what is known as a *choked disc*, which may be seen through the ophthalmoscope. The normal disc is the beginning of the optic nerve in the retina (which is really a part of the brain). Normally it is seen as a slight depression. When choked (papilledema), it is more or less elevated. It leads to the diagnosis of brain tumor. Furthermore, if one side or the other of this nerve is interfered with along its path, various fields of vision will become lost. For example, a growth about the pituitary gland would involve the decussation of the nerve. This would produce a *bitemporal hemianopsia*, whereas if the tumor were behind this area on one or the other side, it would produce a *homonomous hemianopsia*. This would immediately fix the growth in one or the other sides of the occipital lobe or somewhere along the nerve path. Quadrantanopsia means loss of vision in about one-fourth of the visual field. This symptom may lead to a more accurate diagnosis of the site of the lesion.

The *third*, or *oculomotor*, nerve has to do with the control of the muscles of the eye (except the external rectus and superior oblique) and of the upper lids; it also constricts the pupil. When divided or diseased, there is a paralysis of most of the eye muscles and a ptosis of the lids, together with a dilatation of the pupil.

The *fourth*, or *trochlear, nerve* controls the superior oblique muscle. It is rarely injured alone and is usually a part of an ophthalmoplegia. When it is affected, the eye deviates upward and slightly inward.

The *fifth*, or *trigeminal, nerve* is the greatest sensory nerve of the face, having as its three divisions the (1) ophthalmic, (2) maxillary, and (3) mandibular nerves, all of which have their nuclei in the gasserian ganglion. It is of clinical importance chiefly because of the pain that may occur from irritation of this nerve. Such a state is known as *tic douloureux*. The motor part of the fifth nerve is distributed chiefly to the muscles of mastication.

The *sixth*, or *abducens, nerve* supplies the external rectus of the eye and when it is divided or injured the eyeball rotates to the inner side and produces an *internal squint*.

The *seventh*, or *facial, nerve* is the chief motor nerve of the face and supplies the muscles of expression. When it is injured or diseased so that its function is impaired, the muscles on that side of the face will be paralyzed. The paralysis will be complete if the injury is peripheral and partial if the injury is central because of cross innervation. If the patient is asked to smile, his cheek and mouth will be drawn to the opposite side. This condition is known as *Bell's palsy*.

The sensory portion of the seventh nerve is the *nervus intermedius*, the peripheral fibers of which represent parts of the greater superficial petrosal nerve and the chorda tympani branch of the facial; the central fibers form the nervus intermedium. The cells of these fibers lie in the ganglion genicula of the facial nerve. The nervus intermedius contains afferent sensory and vasodilator (parasympathetic) fibers. The taste buds and mucous membrane of the anterior two-thirds of the tongue are innervated by the chorda tympani, and the mucous membrane of the soft palate and posterior part of the nose send impulses by way of the superior petrosal nerve and the sphenopalatine ganglion. Secretory and vasodilator fibers to the lachrymal gland and palate (superior petrosal nerve) and the submaxillary and sublingual glands (chorda tympani) form the efferent components of these nerves.

The *eighth*, or *acoustic, nerve* is the nerve of hearing. Any disease or injury to this nerve will produce an interference with the functions of hearing or of equilibrium (semicircular canals of the middle ear) so that dizziness may be complained of. *Dizziness*, or *vertigo*, denotes loss of equilibrium manifested as a sense of rotation with reference to surrounding objects in space. The vestibular portion of the membranous labyrinth is the end organ responsible for impulses controlling orientation in space or equilibrium. The causes of this distressing symptom include uneven motion (car and sea sickness); cardiac, renal, vascular diseases, pernicious and severe secondary anemia (produce hyperemia and anemia of labyrinth); leucemia and purpura (produce hemorrhage into labyrinth); toxic vertigo caused by alcohol, tobacco, quinine, salicylates; nitrogen embolism (caisson disease, aviator's), Ménièr's symptom complex (allergic); ocular vertigo; lesions of the cerebellum or cerebellopontine angle such as tumors, cysts, abscesses, vascular anomalies which press

THE CRANIAL NERVES

The senses of man are (1) sight—light, form, and color; (2) taste; (3) touch—deformation of the skin, tickle and vibration sense, and the deep sensibility of muscle; (4) temperature—heat and cold; (5) smell; (6) proprioceptive stimuli from the muscles, tendons, and joints, informing the organism of location in space; (7) changes in position in space through the functional activity of the semicircular canals, the utricle, and the saccule; (8) hearing; (9) pain from skin, muscle and blood vessels; (10) visceroceptive stimuli of which persons are usually unconscious but which probably affect vasomotor, respiratory, and cardiac changes reflexly; for example, the inhibition of respiration from distention of the lungs.

The nerves of special senses are twelve in number (called the cranial nerves) and may be listed as follows:

The *first*, or *olfactory, nerve* is the nerve conveying the sense of smell and has its cells in the anterior lobe of the brain. In new growths in this portion of the brain *anosmia* may occur, providing a useful sign to the neurologist in diagnosis.

The *second*, or *optic, nerve* is the nerve of vision. Its importance from a diagnostic standpoint is that in any increase in intracranial pressure of long standing, the venous return and the cerebrospinal fluid circulation are impeded. This results in edema and there will be what is known as a *choked disc*, which may be seen through the ophthalmoscope. The normal disc is the beginning of the optic nerve in the retina (which is really a part of the brain). Normally it is seen as a slight depression. When choked (papilledema), it is more or less elevated. It leads to the diagnosis of brain tumor. Furthermore, if one side or the other of this nerve is interfered with along its path, various fields of vision will become lost. For example, a growth about the pituitary gland would involve the decussation of the nerve. This would produce a *bitemporal hemianopsia*, whereas if the tumor were behind this area on one or the other side, it would produce a *homonomous hemianopsia*. This would immediately fix the growth in one or the other sides of the occipital lobe or somewhere along the nerve path. Quadrantanopsia means loss of vision in about one-fourth of the visual field. This symptom may lead to a more accurate diagnosis of the site of the lesion.

The *third*, or *oculomotor*, nerve has to do with the control of the muscles of the eye (except the external rectus and superior oblique) and of the upper lids; it also constricts the pupil. When divided or diseased, there is a paralysis of most of the eye muscles and a ptosis of the lids, together with a dilatation of the pupil.

The *fourth*, or *trochlear, nerve* controls the superior oblique muscle. It is rarely injured alone and is usually a part of an ophthalmoplegia. When it is affected, the eye deviates upward and slightly inward.

is made on the part of the divided nerve into which the new fibers have grown (Tinel's sign); also by a short chronaxia and by response to faradic stimulation of muscle.

Factors which influence repair are the same as those which affect other tissues (see Chapter 3). However, some special considerations must be given nerve tissue in regard to time of suture of the divided nerve, methods of suture, infection, length of immobilization, soft tissue defects, nerve grafts.

Time of Suture.—Surgical opinion is divided on the proper time for the suture of a divided nerve. Some surgeons believe that if a wound is seen within eight to ten hours and if it is not the result of a high velocity bullet or a tearing injury, primary suture is indicated. If seen after this time, even if the wound is due to a sharp instrument, three to four weeks should elapse before suturing. Indeed there are those who aver that there is a better prospect of a good recovery after an early secondary than after primary suture. This teaching is contrary to the principles we have enunciated in Chapters 3 and 16. Here we stated that primary approximation of the divided nerve stump is always advisable and that failures are due to the six factors described but especially poor technique, inadequate resection of the damaged nerve ends, excessive tension, and lack of immobilization for a long enough period (three weeks at least). The reasons given for delayed suture are: (1) adequate facilities for immediate repair are not always available; (2) the patient may not be in condition to withstand a time-consuming careful repair; (3) intraneural damage is difficult to estimate at the time of injury, especially when made by high velocity bullets or crushing injuries; (4) mobilization and transplantation of the nerve in badly contused tissue may be followed by infection; (5) the epineurium is thin and friable and lacks the tensile strength to hold sutures; (6) often the wound must be extended in order to mobilize the nerve ends; (7) early delayed suture (say eight to ten days) finds the nerve ends edematous; (8) primary approximation so that the nerves do not retract is wrong because neuromas form as well as scars requiring resection of greater lengths; (9) nerves lying free are covered with fibrin and are swollen, whereas those protected by muscle are not fibrosed. In military surgery it is perhaps best to treat the primary wounds as previously outlined (Chapters 3 and 16) and if possible the nerve should be covered by muscle, and then within three to four weeks after the primary wound has healed solidly the nerve may be approximated. In civilian practice if the wound is early (six to eight hours) primary suture may be done after careful débridement. Late wounds (twelve to twenty-four hours), if due to a sharp instrument, may be treated by primary suture and incomplete closure of the soft tissue wound. Contused wounds after eight hours or incised wounds after twenty-four hours should be left open (late late wounds) and nerves should be repaired six to eight weeks later.

on the acoustic nerves; disseminated sclerosis; aural vertigo (trauma to the ear, basal skull fractures involving the labyrinth, concussions, otosclerosis); infections in and around the labyrinth (labyrinthitis and perilabyrinthitis as in mastoid infections); tumors of the acoustic nerve. The common growth involving this nerve is neurofibroma or neurilemmoma (acoustic neuroma).

The *ninth*, or *glossopharyngeal, nerve* innervates the tongue and pharynx. It has some sensory function (taste) on the posterior portion of the tongue and supplies motor fibers to the stylopharyngeus muscles. Secretory and vasodilator fibers to the parotid gland go by way of the tympanic branch, lesser superficial petrosal nerve, and otic ganglion. The sinus nerve, a branch of the glossopharyngeal, carries the afferent fibers of the carotid sinus reflex arc (Chapter 14). Injury or disease of the nerve interferes with swallowing and sense of taste. Inflammation of the sensory part may produce pain in the pharynx and posterior part of the mouth.

The *tenth*, or *vagus nerve* is the chief nerve of the autonomic (*parasympathetic*) nervous system and has branches to the heart, lungs, intestinal tract, bronchi, and gall bladder. It contains sensory, motor, secretory, and perhaps vasodilator fibers to these organs.

The *eleventh*, or *spinal accessory, nerve* supplies the trapezius muscles and when it is cut or diseased there is a drooping of the shoulder. Formerly this nerve was used as a transplant in the event that the facial nerve had been destroyed. The bulbar part fibers join the vagus in the jugular foramen and are distributed in the pharyngeal and recurrent branches of the vagus and innervate the muscles of the larynx (except cricothyroid), the pharynx, and soft palate (except tensor veli palatini).

The *twelfth*, or *hypoglossal, nerve* is purely motor to the muscles of the tongue. Paralysis of one nerve will cause the *tongue to deviate* to the unparalyzed side since it is literally pulled out by muscles which are unopposed.

PERIPHERAL NERVES

We have already considered the pathological changes that occur in a nerve when it is divided and nature's method of repair (Chapter 3). Needless to say, a peripheral nerve is usually a mixed one and contains not only many sensory fibers, but motor fibers as well. Injury to such nerves produces deficiencies in both functions.

War experience has contributed much to the knowledge of nerve regeneration after injury. Operations performed on severed nerves months after injury have revealed that nerve fibers will find their way into distal segments provided the gap is not too great and foreign bodies do not intervene. Nerve function also returns as evidenced by a return of a tingling sensation along the reinnervated field when pressure

The *phrenic nerve* is the chief nerve of the diaphragm. It comes from the cervical plexus. When it is injured or divided, the diaphragm becomes paralyzed on that side and rises to a point of extreme elevation (expiration). The phrenic is often crushed or divided in the treatment of basal pulmonary tuberculosis and chronic empyema to facilitate obliteration of the cavity; also in congenitally short esophagus, esophageal hiatus hernia (at times), esophagectomy, and certain types of congenital diaphragmatic hernia (see Chapters 8, 19, and 20).

Hiccup, or singultus, is said to be due to an irritation of the phrenic nerve. There is a sudden contraction of the diaphragm and a snapping closure of the glottis, which may be due to a spasm of the adductor muscles of the vocal cords or to the sudden inrush of air (Homans). It is commonly seen after some gastric irritation and is usually transient and trivial. However, it may persist for long periods.

Postoperatively it is seen after abdominal operations or in association with renal insufficiency. In addition to its annoyance, it may delay repair of the wound, interfere with nutrition, and so exhaust the patient as to become alarming. Other conditions in which hiccup may occur are peritonitis, intestinal obstruction, paralytic ileus, diaphragmatic injuries, and encephalitis.

Some type of treatment is known to every layman. Such remedies as snuff to produce sneezing, rebreathing in a paper bag, gulping hot water, sweet spirit of niter, etc., are commonly used. Perhaps the most effective treatment is the administration of 5 to 10 per cent mixtures of CO_2 in oxygen. In a recent accident case (fractures of many ribs, with probable diaphragmatic injury) hiccup developed and could not be controlled by CO_2, morphine, codeine, phenobarbital, or other remedies. The phrenic nerve area on the injured side was infiltrated with 1 per cent procaine solution (with Adrenalin), bringing temporary relief, and after three such injections the hiccups ceased.

The *brachial plexus* is made up of fibers from the fourth, fifth, sixth, seventh, and eighth cervical and the first thoracic nerves. It may be injured in childbirth and, if so, there is paralysis of certain arm muscles and disturbances of sensation.

Sensory disturbances are loss of light touch (epicritic sense), pinprick (protopathic sense), and complete anesthesia (except deep muscle sense, which apparently is carried by other nerves than those supplying the skin). Whenever a sensory nerve is injured, the periphery of the area supplied loses the epicritic sense, and the center of the area, the protopathic sense as well. All zones overlap, as do nerve areas normally.

Motor disturbances are chiefly muscular. The location of motor end plates has been well worked out by physiologists and if the appropriate area is stimulated by the galvanic current (on the make or break) or the faradic current (continuously applied), the muscles can be made to contract.

Methods of Suture.—A conventional method of suturing nerves has been described in Chapter 3. This consists of uniting the connective tissue nerve sheath with fine silk sutures or with tantalum wire. Objections to this method of approximation are based on the following observations: (1) inclusion of nerve fibers in each suture, especially in small nerves; (2) knuckling of fibers when sutures are tied; (3) difficulty in introducing sutures evenly and resultant axial rotation with misdirection of fibers into unmatched "geographical" patterns; (4) adhesions to surrounding tissues. Although methods of "splinting" the nerve by the use of plasma clot, fibrinogen-thrombin, Gelfoam and tantalum foil have been advocated in place of sutures, it seems desirable to hold the nerve ends in opposition by carefully introduced silk, cotton, or wire suture. The plasma clot splint may be used as an additional safeguard. However, a graft of subcutaneous tissue around the suture line may be equally effective to prevent vicious adhesions. If the amount of nerve loss is too great to be approximated without tension, then nerve grafts should be employed. As in other tissues, autogenous grafts give the best results although isogenous and homogenous grafts have yielded good results. Regenerating nerve fibers are preceded by Schwann cells and follow the path of proliferating histiocytes. Since the graft gets its blood supply from surrounding tissue, it is better not to cover the graft with plasma clot or other material. The graft is held in place by carefully placed sutures. Autogenous grafts are difficult to obtain except, for example, where all of the nerves of the arm have been severed except the radial. Here it would be justifiable to use part of the ulnar to repair the median in an attempt to regain sensory and motor function on the thumb and forefinger. Nerves should be immobilized for at least three weeks.

Soft Tissue Defects.—Soft tissue defects are treated in accordance with the principles described in Chapter 16. In the late late wounds, reconstructive procedures, such as excision of scars, or inadequate grafts, or correction of bone defects, may include nerve repair at the same time that full-thickness grafts or other corrective procedures are instituted.

Infection.—Infection is a contraindication to primary nerve suture. However, peripheral nerves have a strong resistance to infection and may heal in the presence of an abscess. The same is true of nerve grafts. The destruction of surrounding muscle, tendon, fat, and fascia by the infection leads to the production of much granulation tissue and scar and may thus prevent proper nerve regeneration.

By knowing the various fields which are supplied by such nerves and the various muscles which such nerves may govern, one is able to diagnose the nerve involved and to repair the same if possible. Later, contractions of a muscle on closing or opening of a circuit conveying a direct current will gradually disappear when the "reaction of degeneration" occurs. A few examples of this may be given as illustrations.

Birth Injuries

Erb-Duchenne (upper arm paralysis) includes the fifth and part of the sixth cervical nerve. This would include the axillary and radial, and therefore the arm hangs (paralysis of the abductors of the shoulder), with extension and pronation of the forearm (paralysis of flexors and supinators of forearm); sensory disturbances are slight. The injury may be caused at birth by pulling the head away from the shoulder, or the shoulder may be forced down; in either case the upper cord is involved.

Klumpke, or lower arm, paralysis involves a part of the eighth cervical and first thoracic nerve. This would include the ulnar (intrinsic *muscles of the hand) and a part of the median (long flexors of median).* Pulling up on the shoulder may produce the injury at birth.

The entire brachial plexus may be injured at birth when undue force is exerted in difficult deliveries. The treatment is, on the whole, unsatisfactory. Attempts at repair have been largely unsuccessful because of extensive scarring and injury. Massage and electrical stimulation together with proper muscle support will permit fibers to regenerate if the neurolemma has not been too badly torn and distorted.

Incised wounds and other injuries of the brachial plexus should be repaired surgically. The results are not as good as on single nerve injuries, and regeneration is slow due to the distance between the plexus and the hand. However, many excellent results have been reported. Rarely the proximal ends of the less important nerves (long thoracic, anterior thoracic) may be sutured to the distal end of more important nerves (suprascapular, musculocutaneous, axillary nerves) where an anastomosis of the cut ends of the plexus is not feasible. Physical therapy and the attempts to move the arm and fingers are helpful.

Industrial Accidents

In industrial accidents the nerves of the arm and leg may be injured. The position of the nerve, the muscles involved, and the sensory field supplied give the surgeon an accurate diagnosis. For example, division of the *radial nerve* gives rise to *wrist drop* because this nerve supplies most of the extensor muscles of the wrist and fingers. If the injury is low, small sensory fields over the back of the thumb and the forefinger will also become impaired in function. If injured in the upper arm and just above the wrist, it differs from the lower arm in *producing more sensory involvement in* the two former because the dorsal cutaneous comes off high and in the lower forearm fibers from the musculocutaneous join it. Injury to the posterior interosseous branch does not produce wrist drop or sensory disturbances. Dorsiflexion is preserved by the extensor carpi longus. Paralysis of the extensor digitorum communis renders extension of the proximal phalanges impossible, but the distal phalanges retain their movement (interossei and lumbricales).

Four to seven days after division of a nerve there is no response to the faradic current, and after ten days, a sluggish response to the galvanic. This loss of response to faradic and sluggish response to galvanic stimulation is known as the *reaction of degeneration*. If it persists, muscle atrophy and fibrosis occur, but recovery is possible. If there is a *complete reaction of degeneration* (no response at all to galvanic stimulation), recovery is usually not possible. In addition to sensory and motor disturbances, the part becomes cold and blue, indicating sympathetic nerve disturbance.

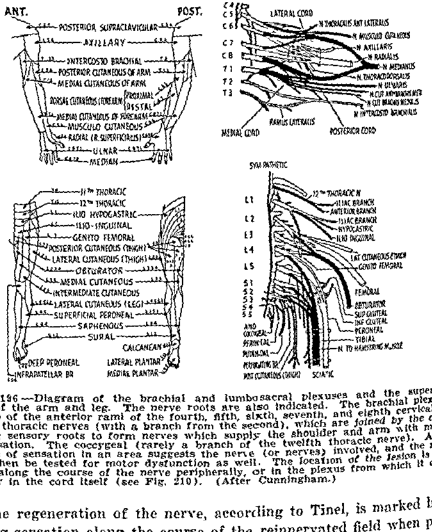

Fig. 196.—Diagram of the brachial and lumbosacral plexuses and the superficial nerves of the arm and leg. The nerve roots are also indicated. The brachial plexus is made up of the anterior rami of the fourth, fifth, sixth, seventh, and eighth cervical and the first thoracic nerves (with a branch from the second), which are joined by the corresponding sensory roots to form nerves which supply the shoulder and arm with motion and sensation. The coccygeal (rarely a branch of the twelfth thoracic nerve). A disturbance of sensation in an area suggests the nerve (or nerves) involved, and the nerve should then be tested for motor dysfunction as well. The location of the lesion is then sought, along the course of the nerve peripherally, or in the plexus from which it originates, or in the cord itself (see Fig. 210). (After Cunningham.)

The regeneration of the nerve, according to Tinel, is marked by a *tingling sensation along the course of the* reinnervated field when pressure is made on the regenerated part of the nerve (that is, peripheral to the part sutured or anastomosed). *The motor part* requires five to seven months or longer before any tonicity is seen in the muscles. Then *voluntary motion slowly returns.* In addition to massage, heat, electrical stimulation, and splinting (to prevent contractures by opposing muscles), *the patient* must try to use his muscles to force stimuli into the regenerated axis cylinders(?).

(pinprick), then laterally to half of third toe and the lateral part of the lower leg. The *tibial nerve* is comparable to the median and ulnar nerves (plantar flexors) and is seldom injured.

Inflammations

In addition to the preceding traumatic considerations, there may be many other causes of nerve disorder which may produce an inflammation of the nerve or an irritation. Such disorders have been called *neuritis* (inflammation of nerve) in the former and *neuralgia* (painful nerve) in the latter event.

A brief grouping of such causes is suggested in the following outline (Homans):

Kinds of Peripheral Neuritis and Neuralgia

1. Injury to peripheral nerves, as in sepsis and fibrosis
   a. Tic douloureux
   b. Neurofibrositis (amputation neuroma)
2. Disease involving nerve trunks
   Septic processes; pressure (abnormalities of the spinal column)
   Multiple neuritis (alcohol, lead, arsenic)
   Tumors (as neurofibromatosis, neurilemmoma)
   Causalgia and ascending neuritis
3. Lesions of posterior roots or posterior root ganglia (herpes)
4. Psychalgias (coccygodynia)

Another *classification into general and local types* is as follows (Cobb and Coggeshal):

1. Generalized polyneuritis
   a. Virus diseases (such as poliomyelitis, herpes, smallpox, epidemic encephalitis, rabies)
   b. Bacterial diseases (such as pneumonia, diphtheria, typhoid, chorea)
   c. Metabolic or deficiency diseases (pellagra, beriberi, sprue, etc.)
   d. Chemical poisoning such as arsenic or lead
2. Localized neuritis
   a. Infections (diphtheria, tetanus, streptococcus, leprosy)
   b. Mechanical causes (pressure, tumor, edema, fibrosis, trauma or local asphyxia, as in Volkmann's contracture)

One of the most common errors of the laity and even of physicians is to call any pain a neuritis. It is true that the pain is a neuralgia, which is another way of saying "pain in a nerve." This is meaningless from a diagnostic point of view. For example, "neuritis" of the arm is commonly a subdeltoid bursitis; neuritis of the leg, sacroiliac disease, sometimes a protruding nucleus pulposus, rarely a spinal cord tumor.

It will be seen, then, from this discussion that pain (sensory) or paralysis (motor) means nerve involvement. It must be decided whether or not the nerve is really affected (neuritis) or is stimulated by disease in its path (neuralgia). Then by a careful study of symptoms and signs,

There is paralysis of extensors of the thumb and the long abductor of the thumb, preventing extension of the thumb and its abduction in the plane of the palm. Thus the thumb reposes in a position of slight flexion, being immediately ventral to the index finger. The posterior interosseous branch may be repaired with a good chance of regeneration.

The *median nerve* supplies the flexors of the wrist except the flexor carpi ulnaris and fingers, the pronators of the forearm, and the opponens and abductor pollicis muscles of the thumb. When the median nerve is injured, the thumb cannot be rolled over on the palm or make the letter "o" with the little finger, nor can it be abducted at right angles to the plane of the palm. The median nerve supplies the sensory area on the palm, from the middle of the ring finger radialward to the thumb, and the area on the back of the second, third, and fourth fingers over their distal portions. These symptoms are characteristic and occur when the median is injured in the region of the elbow. Few symptoms are present when the nerve is injured in the wrist. This is due to the fact that there are no branches in the upper arm, but there are communications with the ulnar in the proximal forearm and in the palm through its cutaneous branches.

The *ulnar nerve*, which is frequently injured, controls the intricate actions of the fingers so that after injury of this nerve the thumb may not be adducted (adductor pollicis) to the side of the hand, and the fingers—particularly the fourth (ring) and fifth (little finger)—may not be extended at the interphalangeal joints nor flexed at the metacarpophalangeal joints (claw hand). The fingers cannot be separated and brought together (interossei). The sensory area supplied by the ulnar is the ulnar one-half of the fourth finger and the anterior part of the fifth finger and extends posteriorly over about the same area. The ulnar lies close to the median and brachial artery in the arm. There are no branches until the forearm. Here it supplies the flexor carpi ulnaris and medial half of the flexor digitorum profundus. The two terminal branches are a superficial, which is purely cutaneous, and a deep, which is purely muscular, supplying the flexor brevis and abductor digiti quinti, opponens digiti quinti, and branches to the interossei, third, and fourth lumbricales, adductor policis, and deep part of flexor policis. It communicates with the median and radial.

If the *common peroneal nerve* in the leg is injured, a situation comparable to wrist drop (from radial nerve injury in the arm) will be seen. However, here it will be *foot drop*. Injury to this nerve is apt to occur when casts are used in the lower leg about the knee, or when operations are done on the fibula, for the nerve winds around the neck of the fibula. Injury to the common peroneal will produce disturbed sensation over an area on the dorsum of the foot, extending as a triangle, with the base over the lateral half of the big toe and medial half of the second toe

ones which are the seat of neurofibrositis, resection of the neuroma, neurectomy, reamputation at higher levels fail to produce a cure.

Experimental evidence is against the opinion that pain impulses traverse the sympathetic ganglion. They probably follow mixed nerves to enter the spinal cord by the posterior roots. However, resection of the posterior roots frequently fails to give relief. The best prophylaxis is, first, an amputation if possible which will permit weight bearing on the stump (Gritti-Stokes; Symes) rather than around the circumference by a boot; second, as little handling of nerves as possible; third, division of the nerve with a sharp scalpel without previous crushing or injection and without subsequent injection of alcohol; and, fourth, division at a high level so that axis cylinders will regenerate into the muscle far above the site of weight-bearing, granulation tissue, and subsequent scarring.

The symptoms and signs include (1) the pain which may be local or along the course of the nerve or the spinal segment; (2) trophic changes; (3) vasomotor disturbances; (4) pain (if present before operation) projected to the same area in the phantom; (5) sensations—warmth, burning, throbbing, piercing, cramping, or cutting.

Treatment is variable and, like the causalgia states, is often ineffective, due to strong psychologic factors. Any local irritation or tumor should be removed; in addition, vasomotor disturbances are benefited by local infiltration with procaine (1 per cent) of the paravertebral sympathetic nerves, and if this is effective but not lasting, sympathetic ganglionectomy is indicated. Where amputation has been done for vascular disease, tetraethylammonium bromide or Priscoline may be useful if sympathetic ganglionectomy is contraindicated, because of the poor physical condition of the patient.

In the more intractable cases anterolateral chordotomy may be helpful. As a last resort cerebral tractotomy may be necessary. But even then the "phantom pain" may persist in the amputated extremity. Therefore, psychotherapy is extremely helpful in all of these patients.

Group 2. Disease Involving Nerve Trunks.—

Causalgia has been discussed in Chapter 6 under Indirect Injury Due to Circulatory Disorders because of the associated vasomotor phenomena. Weir Mitchell first described this syndrome and ascribed its origin to a partial or incomplete injury of a major nerve trunk. The causalgia-like state referred to in Chapter 6 may be due to relatively minor injuries, or indeed the origin may be obscure or entirely unknown. The cutaneous hyperalgesia, burning, rasping pain, and local increase in blood flow with edema to the part involved is a classical picture. Usually the median or sciatic nerves are involved. Almost all forms of treatment have been tried, including direct surgical attack on the injured nerve (neurolysis), drugs, physiotherapy, fever therapy, periarterial sympathectomy, cervico-

the nerve or nerves affected must be found and finally the cause or causes for the condition must, if possible, be discovered. Then treatment will be effective.

However in spite of the most painstaking examination, this may be difficult. This is due to the fact that chronic irritation of a sensory nerve pathway may involve peripheral, spinal, and cortical levels. This will be more apparent if the diagram of a cross section of the spinal cord is consulted. Sensory nerves may be irritated by injury or inflammation or new growth as follows: (1) peripherally in the skin, (2) along the sensory root distal to the dosal root ganglion, (3) in the dorsal root ganglion, (4) proximal to it, (5) in the dorsal horn cells, or (6) the whole afferent neuron may be involved. Similarly the other compartments of the reflex arc may be involved by disease but not producing pain: (1) connector neuron by cord tumor, syringomyelia, etc.; (2) anterior horn cells by anterior poliomyelitis, and (3) the motor nerve trunk anywhere along its course as indicated by local or systemic factors. Furthermore, stimulation anywhere along the course of a sensory nerve may give rise to symptoms and signs locally in the skin, later over the course of the nerve, then a wide zone involving the dorsal cord, and finally the sensory cortex. Thus an amputation neuroma, phantom limb, causalgia, and psychalgia become closely related entities. Moreover, as a result of connector or efferent neuron stimulation, the motor effects may produce pain, or as a result of immobility due to pain secondary changes occur which in themselves are painful.

Thus an outline on neuralgia will be helpful if the foregoing facts are borne in mind and if, in addition, the possibilities are considered, beginning with the periphery where most causes are found and working centrally. A few special types of neuralgia need further consideration.

Group 1. Injury to Peripheral Nerves.—

Neurofibrositis is usually referred to as an *amputation neuroma*, yet the lesion is not a true neuroma but a bundle of axis cylinders, and what is more important, the most painful states do not present a tumor at all. In this group belong *"phantom limb"* with little or severe pain in the amputated extremity. The cause of these pains is not clear and may be due to local irritation of bundles of axis cylinders or a projection from sensory areas of the cerebral cortex. Some have ascribed the condition to psychogenic causes and have branded the patient as psychoneurotic. This is probably not true, although the phantom sensation may be a projection arising from the postcentral sensory association areas in the cerebral cortex.

No doubt the origin is in small neuromas in the stump. It is inconceivable that an operation of any kind can be accomplished without end bulbs or neuromas forming. These may be very small but any stimulus, physical or emotional, may excite them. However, except in the large

ones which are the seat of neurofibrositis, resection of the neuroma, neurectomy, reamputation at higher levels fail to produce a cure.

Experimental evidence is against the opinion that pain impulses traverse the sympathetic ganglion. They probably follow mixed nerves to enter the spinal cord by the posterior roots. However, resection of the posterior roots frequently fails to give relief. The best prophylaxis is, first, an amputation if possible which will permit weight bearing on the stump (Gritti-Stokes; Symes) rather than around the circumference by a boot; second, as little handling of nerves as possible; third, division of the nerve with a sharp scalpel without previous crushing or injection and without subsequent injection of alcohol; and, fourth, division at a high level so that axis cylinders will regenerate into the muscle far above the site of weight-bearing, granulation tissue, and subsequent scarring.

The symptoms and signs include (1) the pain which may be local or along the course of the nerve or the spinal segment; (2) trophic changes; (3) vasomotor disturbances; (4) pain (if present before operation) projected to the same area in the phantom; (5) sensations—warmth, burning, throbbing, piercing, cramping, or cutting.

Treatment is variable and, like the causalgia states, is often ineffective, due to strong psychologic factors. Any local irritation or tumor should be removed; in addition, vasomotor disturbances are benefited by local infiltration with procaine (1 per cent) of the paravertebral sympathetic nerves, and if this is effective but not lasting, sympathetic ganglionectomy is indicated. Where amputation has been done for vascular disease, tetraethylammonium bromide or Priscoline may be useful if sympathetic ganglionectomy is contraindicated, because of the poor physical condition of the patient.

In the more intractable cases anterolateral chordotomy may be helpful. As a last resort cerebral tractotomy may be necessary. But even then the "phantom pain" may persist in the amputated extremity. Therefore, psychotherapy is extremely helpful in all of these patients.

Group 2. Disease Involving Nerve Trunks.—

Causalgia has been discussed in Chapter 6 under Indirect Injury Due to Circulatory Disorders because of the associated vasomotor phenomena. Weir Mitchell first described this syndrome and ascribed its origin to a partial or incomplete injury of a major nerve trunk. The causalgia-like state referred to in Chapter 6 may be due to relatively minor injuries, or indeed the origin may be obscure or entirely unknown. The cutaneous hyperalgesia, burning, rasping pain, and local increase in blood flow with edema to the part involved is a classical picture. Usually the median or sciatic nerves are involved. Almost all forms of treatment have been tried, including direct surgical attack on the injured nerve (neurolysis), drugs, physiotherapy, fever therapy, periarterial sympathectomy, cervico-

dorsal and lumbosacral sympathectomy, and psychotherapy. Of all forms of treatment, sympathectomy and psychotherapy give the best and most lasting results.

Scalenus anticus syndrome. Normally the lowest cord of the brachial plexus passes behind the scalenus anticus muscle and over the first rib. The subclavian artery comes out of the thorax behind the muscle and emerges over the first rib in the angle formed by the scalenus anticus and the first rib. If a cervical rib is present, the nerves and artery are forced to make a more acute bend behind the muscle and over this rib, exposing both to an irritation which may give rise to symptoms as follows: pain over the shoulder, down the arm along the course of the

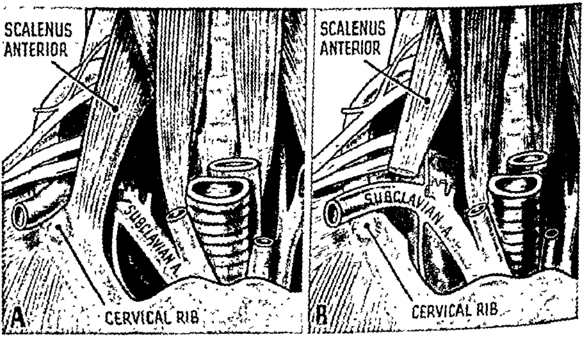

Fig. 197.—Scalenus anticus syndrome. *A*, Diagram illustrating the possible cause of arm pain and vasomotor phenomena. *B*, Division of the anterior scalene muscle and its effect upon this pressure

median and ulnar nerve. If the patient turns his head toward the affected side and raises the elbow, the pain is relieved, and the pain increases if the elbow is lowered. Sometimes vasomotor phenomena appear such as coldness with sweating and bluish discoloration. If much pressure is present on the subclavian, the pulse will be feeble and the blood pressure on the affected side will be lower. If the patient takes a deep breath, elevates his chin, and turns it toward the affected side, pulsations may be obliterated in the subclavian, brachial, and radial. Sometimes feebleness of pulsation is due to atheroma at the site of pressure on the subclavian. This must be remembered during operation, as a "blow out" may occur. Gangrene of the fingers has been reported, and in this way this syndrome resembles Raynaud's disease. Although

the gangrene may be due to spasm or atheroma with thrombosis, a dislodged thrombus, producing embolism, may also be a cause.

Similar symptoms may be present without a cervical rib due to spasm of the scalenus anticus or in congenital malformations of the first rib (rudimentray structure terminating in a synostosis or pseudoarthrosis with the second rib, or free in a free end in the soft tissues with or without a fibrosis band attached to the manubrium).

The syndrome must also be differentiated from cervical arthritis, carcinoma of the lung (Pancoast or superior sulcus carcinoma), metastatic carcinoma of the nodes at the thorax apex, herniation of lower cervical discs, tumors of peripheral nerves, and, very rarely, thromboangitis.

Diagnosis includes careful examination, x-ray studies, and injection of the scalenus muscle with procaine which should give relief if due to spasm.

Treatment in mild cases consists of injection of the muscle with procaine, 1 per cent and exercise of the involved shoulder to strengthen the trapezius and other muscles which elevate the shoulder. In more severe cases treatment includes sectioning of the scalenus anticus tendon at its attachment to the first rib, also any fibers of the scalenus medius which seem tense; resection of the cervical rib or abnormal first thoracic rib must be done to relieve pressure in some cases.

Septic processes and *pressure* involving nerve trunks and producing nerve pain include sinusitis (glossopharyngeal neuralgia), protrusion of one or more intervertebral discs, hypertrophy of ligamenta flava, fractures of the vertebra, spondylitis, radiculitis, traumatic spondylitis, spondylolisthesis, Pott's disease, posttraumatic spondylitis (Kümmel's disease).

Tumors of *peripheral nerves* include neurofibroma and neurilemmoma. The latter is also known as perineural fibroblastoma or schwannoma and is closely related to the carcinoid tumors of the small intestine and appendix which arise in nerve tissue which are related to argentaffin or chromaffin cells. The neurilemma is a membrane made of Schwann's cells and a constricted portion (nodes of Ranvier). The neurilemma as a whole is not connective tissue but is a membrane all its own and is ectodermal in origin. The tumors do behave as connective tissue neoplasms as well as carcinomas. The peripheral types are usually benign. Sometimes they show areas of fatty and cystic degeneration. We removed a cystic perineural fibroblastoma from the axilla of a 40-year-old woman. Our clinical diagnosis was cystic lymphangioma. Neurofibroma does not often occur singly but is usually disseminated, as in von Recklinghausen's disease (see Chapter 16). Ganglioneuromas are usually found in the retroperitoneal or posterior mediastinal spaces. Neuproepitheliomas are rare but highly malignant and require amputation of the extremity if they are present in a limb.

dorsal and lumbosacral sympathectomy, and psychotherapy. Of all forms of treatment, sympathectomy and psychotherapy give the best and most lasting results.

Scalenus anticus syndrome. Normally the lowest cord of the brachial plexus passes behind the scalenus anticus muscle and over the first rib. The subclavian artery comes out of the thorax behind the muscle and emerges over the first rib in the angle formed by the scalenus anticus and the first rib. If a cervical rib is present, the nerves and artery are forced to make a more acute bend behind the muscle and over this rib, exposing both to an irritation which may give rise to symptoms as follows: pain over the shoulder, down the arm along the course of the

median and ulnar nerve. If the patient turns his head toward the affected side and raises the elbow, the pain is relieved, and the pain increases if the elbow is lowered. Sometimes vasomotor phenomena appear such as coldness with sweating and bluish discoloration. If much pressure is present on the subclavian, the pulse will be feeble and the blood pressure on the affected side will be lower. If the patient takes a deep breath, elevates his chin, and turns it toward the affected side, pulsations may be obliterated in the subclavian, brachial, and radial. Sometimes feebleness of pulsation is due to atheroma at the site of pressure on the subclavian. This must be remembered during operation, as a "blow out" may occur. Gangrene of the fingers has been reported, and in this way this syndrome resembles Raynaud's disease. Although

vitamin B; local neuralgia due to chronic bursitis is only relieved when the irritated bursa is treated by x-ray or removal. Postherpetic neuritis may be helped by physiological salt injections within the roots and in addition by thiamine chloride (vitamin B_1) orally; the sciatic pain produced by a protruding intervertebral disc is relieved by removal of the disc.

THE AUTONOMIC NERVOUS SYSTEM

Sympathetic and Parasympathetic Systems

The nervous system of the body may be said to be in two distinct departments: that which governs voluntary actions and that which is self-governing or controls involuntary actions. The former, as we have seen, is known as the central nervous system and the latter has been called the autonomic nervous system. It is easy to understand why the body must have such a mechanism. The heart works automatically, as do the lungs, intestines, bladder, and glands of internal secretion. However, either system affects the other.

The central nervous system may be said to create the environment (that is, specific action), whereas the autonomic nervous system makes it possible for an individual to become adapted to his environment (more general action). Man is a delicate, and yet a very stable, animal. He is sensitive to sudden changes in temperature, yet his blood temperature stays the same whether he be at the North Pole or at the Equator. If he exercises, more sugar is used and more lactic acid is formed. To offset this, glycogen is taken from the liver and lactic acid is oxidized to carbon dioxide, which is volatile and is given off. To facilitate this, blood pressure, heart rate, and respiration are increased. Thus man maintains his stability (homeostasis, as Cannon has termed it).

The difference between a frog (a cold-blooded animal), who is the victim of its environment, and man (who is a warm-blooded animal) is at least in a great measure due to the control of the autonomic nervous system. Such functions as the stability of the body temperature, the rate of respiration, the successful control of the pH and osmotic index of the blood, the activity of the glands of internal secretion, the mobilization of leucocytes and antibodies, immunities and sensitizations, water balance, vascular adjustments, metabolism of fats and sugars are all partially governed by, and in turn affect, this mechanism.

Anatomically, the autonomic (or vegetative) nervous system is composed of two distinct parts: the sympathetic and the parasympathetic systems.

The *sympathetic* system is found in a series of ganglia lying on either side of the spinal column in the thoracic and lumbar regions. These ganglia are little, white, bean-shaped or flat bodies that are joined to the central nervous system by two sets of fibers: the *white rami communicantes* or *preganglionic* fibers, which run from the anterior horn cells

Group 3. Lesions of Posterior Roots or Posterior Root Ganglia.—Lesions of posterior roots or posterior root ganglia include herpes zoster (shingles). This disease is caused by a virus in all probability and may be contagious. Its relationship to chicken pox has been noted. The severe pain which follows the course of the nerves involved precedes the blisters which appear later, and the pain may remain after cutaneous manifestations have disappeared (postherpetic neuralgia). The important fact to remember is that the pain often mimics visceral disease (gall bladder, pleurisy, appendix, etc.) Treatment is unsatisfactory but pain may be relieved by injection of the nerve roots with procaine solution in physiological saline.

Intercostal pain is important because of its effects on respiration (see Chapter 19). Stimulation of the central end of any intercostal nerve causes a reflex inhibition of respiration and a concomitant fall in blood pressure. The lower intercostal nerves (7 to 12) elicit a greater response than do the upper. Also, stimulation of sensory or intercostal fibers in the diaphragm causes reflex contraction of the abdominal musculature through a reflex connection with other lower intercostal nerves. These observations explain the abdominal and thoracic symptoms in intercostal neuralgia from any cause.

Group 4. Psychalgias.—Psychalgias include many different varieties of neuralgia. However, the term is often loosely used to cover unexplained causes of pain. In this group coccygodynia is often listed, yet occasionally a painful coccyx may be due to a glomus tumor over the coccyx or a bursitis of the sacrococcygeal bursa. The treatment will therefore depend on the cause, and certainly removal of the coccyx rarely produces a cure unless in the removal a glomus tumor or chronically inflamed bursa is also removed. Undoubtedly psychotherapy helps.

Treatment of Neuritis.—Obviously the treatment depends on the cause. Types of treatment may be listed under the following heads:

1. General (treatment of the infection, the deficiency, or the chemical cause)
2. Local
   a. Removal of the pressure, tumor, or fibrosis
   b. Injection of nerve with procaine (for diagnosis), or alcohol (temporary relief), or salt solution (epineural injection) to allay inflammation and perhaps lift the nerve off of its bed.
   c. Excision of the nerve (unmyelinated portion for permanent relief)
   d. Excision of the nerve cells (in those of the semilunar ganglion for tic douloureux
   e. Chordotomy for inoperable carcinoma

To give some examples of treatment, general polyneuritis due to vitamin deficiency may be relieved by supplying an adequate intake of

vitamin B; local neuralgia due to chronic bursitis is only relieved when the irritated bursa is treated by x-ray or removal. Postherpetic neuritis may be helped by physiological salt injections within the roots and in addition by thiamine chloride (vitamin B_1) orally; the sciatic pain produced by a protruding intervertebral disc is relieved by removal of the disc.

THE AUTONOMIC NERVOUS SYSTEM

Sympathetic and Parasympathetic Systems

The nervous system of the body may be said to be in two distinct departments: that which governs voluntary actions and that which is self-governing or controls involuntary actions. The former, as we have seen, is known as the central nervous system and the latter has been called the autonomic nervous system. It is easy to understand why the body must have such a mechanism. The heart works automatically, as do the lungs, intestines, bladder, and glands of internal secretion. However, either system affects the other.

The central nervous system may be said to create the environment (that is, specific action), whereas the autonomic nervous system makes it possible for an individual to become adapted to his environment (more general action). Man is a delicate, and yet a very stable, animal. He is sensitive to sudden changes in temperature, yet his blood temperature stays the same whether he be at the North Pole or at the Equator. If he exercises, more sugar is used and more lactic acid is formed. To offset this, glycogen is taken from the liver and lactic acid is oxidized to carbon dioxide, which is volatile and is given off. To facilitate this, blood pressure, heart rate, and respiration are increased. Thus man maintains his stability (homeostasis, as Cannon has termed it).

The difference between a frog (a cold-blooded animal), who is the victim of its environment, and man (who is a warm-blooded animal) is at least in a great measure due to the control of the autonomic nervous system. Such functions as the stability of the body temperature, the rate of respiration, the successful control of the pH and osmotic index of the blood, the activity of the glands of internal secretion, the mobilization of leucocytes and antibodies, immunities and sensitizations, water balance, vascular adjustments, metabolism of fats and sugars are all partially governed by, and in turn affect, this mechanism.

Anatomically, the autonomic (or vegetative) nervous system is composed of two distinct parts: the sympathetic and the parasympathetic systems.

The *sympathetic* system is found in a series of ganglia lying on either side of the spinal column in the thoracic and lumbar regions. These ganglia are little, white, bean-shaped or flat bodies that are joined to the central nervous system by two sets of fibers: the *white rami communicantes* or *preganglionic* fibers, which run from the anterior horn cells

of the spinal cord to the ganglion, and the *gray rami communicantes* or *postganglionic* fibers, which run from the ganglion to the motor nerve. The preganglionic fibers may end in the ganglion, or go up or down the ganglionic chain, or go straight through the ganglion, so that an impulse has a more or less mass effect rather than a specific, local one. Furthermore, the sympathetic nervous system has outlying ganglia, such as the celiac and inferior mesenteric, whose pre- and postganglionic fibers make up the splanchnic nerves, which govern the action of the gastrointestinal

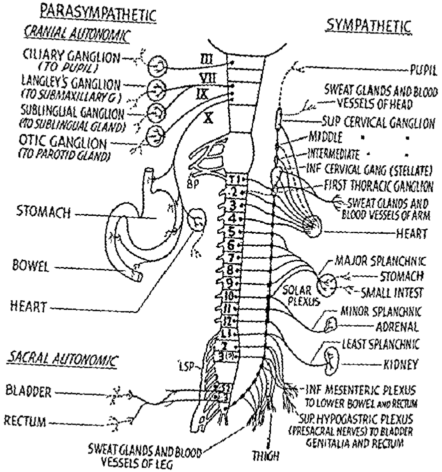

Fig. 198.—Diagram of the autonomic nervous system, showing the sympathetic and parasympathetic systems. BP, brachial plexus; LSP, lumbosacral plexus. (After W. Langdon Brown and Homans.)

tract. And lastly, the sympathetics are intimately related to the adrenal gland, the medulla of which is derived from nerve tissue, so that stimulation of sympathetic nerves may excite the production of adrenaline, which creates a synergistic effect.

Although painful states may be relieved by dividing autonomic nerves, the amelioration is due to a division of true sensory neurons traveling with the autonomic fibers or to a relaxation of the organ as a result of a division of efferent sympathetic or parasympathetic fibers. No *afferent* autonomics have been described.

Impulses are transmitted from the viscera by afferent fibers which pass through the various plexuses and reach the central nervous system through the pelvic, lumbar, splanchnics (greater, lesser, and least splanchnic) and vagus nerves. The afferent fibers of the vagus have their cells in the ganglion jugulare and ganglion nodosum and their central processes in the dorsal nucleus of the vagus. From here connections are made with efferent parasympathetic pathways to complete the reflex arc. The afferent fibers of the pelvic nerve have their cell bodies in the posterior root ganglia of the second, third, and fourth sacral. The afferent fibers of the sympathetic division have their cells in the posterior spinal nerve root ganglia from the first thoracic to the third lumbar. None arise from sympathetic ganglia. They reach the sympathetic trunk by way of the white rami communicantes and are distributed to the viscera along with the corresponding efferent fibers, although afferent fibers are not interrupted in any of the sympathetic ganglia. Some enter the spinal nerves by way of the gray rami for distribution to the limbs.

The *parasympathetic* system originates in the cranial and in the sacral region. The preganglionic fibers are long, the postganglionic fibers short, arising in the glands or muscles they innervate (as the plexus of Auerbach and Meissner) and in the intestinal tract (plexus myentericus and submucosus). The parasympathetic system is partially antagonistic to the sympathetic, and it has been said that whereas the sympathetic nervous system is the "spending" system, the parasympathetic system is the "saving" or "storing" system. When we consider their respective actions, this statement will be more apparent.

The most important nerve of the parasympathetic system is the *vagus*. It has branches to the heart, lungs, and gastrointestinal tract. The sacral parasympathetics control the bladder, colon, rectum, and genital organs. Unlike those of the sympathetic system, the postganglionic fibers lie in the organ itself.

Listed here are a few of the differences between the two systems. It may be said in general that the sympathetics and parasympathetics may be antagonistic to each other but are not necessarily so.

SYMPATHETIC	PARASYMPATHETIC
Vasoconstrictors Sweating	No opposing fibers
Gooseflesh	
Accelerate the heart	Inhibit the heart
Dilate the pupil *and widen palpebral* fissure	Constrict pupil *and narrow palpebral* fissure
Inhibit peristalsis of small and large intestine	Increase peristalsis of small and large intestine
Inhibit antral movements and usually inhibitory to pyloric sphincter	Increase stomach movements and usually excitatory to pyloric sphincter
Diminish secretion	Increase secretion
Relax the bladder and rectum and constrict the sphincters	Contract bladder and rectum and relax sphincters

of the spinal cord to the ganglion, and the *gray rami communicantes* or *postganglionic* fibers, which run from the ganglion to the motor nerve. The preganglionic fibers may end in the ganglion, or go up or down the ganglionic chain, or go straight through the ganglion, so that an impulse has a more or less mass effect rather than a specific, local one. Furthermore, the sympathetic nervous system has outlying ganglia, such as the celiac and inferior mesenteric, whose pre- and postganglionic fibers make up the splanchnic nerves, which govern the action of the gastrointestinal

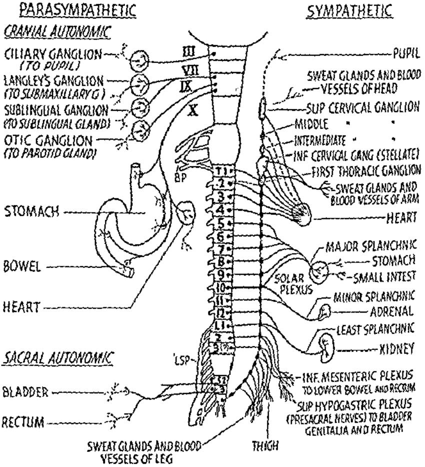

Fig. 198.—Diagram of the autonomic nervous system, showing the sympathetic and parasympathetic systems. BP, brachial plexus; LSP, lumbosacral plexus. (After W. Langdon Brown and Homans.)

tract. And lastly, the sympathetics are intimately related to the adrenal gland, the medulla of which is derived from nerve tissue, so that stimulation of sympathetic nerves may excite the production of adrenaline, which creates a synergistic effect.

Although painful states may be relieved by dividing autonomic nerves, the amelioration is due to a division of true sensory neurons traveling with the autonomic fibers or to a relaxation of the organ as a result of a division of efferent sympathetic or parasympathetic fibers. No *afferent* autonomics have been described.

It is thought that there are centers in the brain (around the third ventricle and lateral to the infundibulum) which control the entire sympathetic nervous system. These centers are under reflex and psychic control.

The *parasympathetic* or *energy-storing* system helps stabilize overactivities of the sympathetics. *Cardioinhibitor nerves* slow the heart. Other nerves stimulate the salivary and digestive glands to activity and promote peristalsis. In this way the parasympathetic system helps digest food; it also aids in excretion (to allow more food to be digested). The sacral parasympathetics empty the rectum and relax the anus and cause contraction of the bladder (detrusor muscle) and relaxation of the sphincter.

Perhaps the autonomics act through chemical substances, *sympathin* and *parasympathin*, which are formed between the nerve ending and the cell. Sympathin possesses the properties of adrenaline (adrenergic); *parasympathin, those of acetylcholine* (cholinergic).

The Action of Drugs Upon the Autonomic Nervous System

Adrenaline has the same effect as stimulation of the *sympathetics*. Sweating is an exception. Denervated effector organs are sensitized to the action of adrenaline. Vasoconstriction occurs everywhere except in the coronaries, the vessels in the intestines, and perhaps skeletal muscles. Pulmonary vessels are unaffected, but in large doses there is vasocontriction and dilation of bronchioles.

Pilocarpine causes *parasympathetic* effects by acting directly upon *the effector cell. These effects are contraction of pupil, cardiac inhibition*, contraction of smooth muscle is bronchioles and alimentary tract, secretion from salivary, gastric, bronchial, and sweat glands.

Muscarine acts like pilocarpine in most of its effects. In addition, it causes vasodilatation. The action is directly on the effector cell.

Choline and its ester, *acetylcholine*, cause *parasympathetic* effects by acting directly on the effector cell. These effects are cardiac inhibition, contraction of smooth muscle of alimentary canal and bladder wall, secretion of saliva, tears, and sweat, dilation of arterioles and fall in blood pressure. Blood and tissue fluids contain an enzyme, cholinesterase, which inactivates acetylcholine. Physostigmine inhibits the action of cholinesterase; therefore, when given with acetylcholine, the latter's action is greatly intensified.

Physostigmine or *eserine* causes *parasympathetic* effects by inhibiting the action of cholinesterase and so permitting the cholinester liberated at the nerve endings to exert its full effects.

Atropine neutralizes parasympathetic effects by acting directly on the effector cell, thus preventing the action if not the liberation of acetylcholine. It is antagonistic to pilocarpine and muscarine. Thus there is an increase in pulse rate, dilation of pupils, decrease in secretion of saliva

The sympathetic and parasympathetic systems in the thorax act differently from the way they act in the rest of the body. For example, the sympathetics carry the cardioaccelerator nerves, and the vagus (parasympathetic) carries the cardioinhibitory nerves. Whereas over the entire body the sympathetics cause constriction of blood vessels, in the heart the sympathetics cause vasodilatation and parasympathetics cause vasoconstriction. The pulmonary circulation is probably not under vasomotor control. In experimental animals (dog) vasoconstrictor as well as vasodilator fibers are found in the sympathetics and the vagus. The prevailing opinion is that vasoconstrictors are predominantly in the sympathetics as in the periphery of the body. However, it is unlikely that effects of exercise, for example, would cause increased activity without provision for adequate blood supply (see Chapter 19).

The sympathetics cause dilatation of the finer bronchi, and the parasympathetics, constriction. It is well known that division of the sympathetics often relieves bronchiolar spasm in asthma. This may not be as paradoxical as it seems, for improvement may be due to the vasoconstriction which ensues, due to the free action of adrenaline on the sympathectomized bronchioles.

Pilocarpine, histamine, and foreign proteins cause bronchiolar spasm. Animals who have died of anaphylactic shock show a constriction of the bronchioles. Air is trapped in the alveoli and the lungs fail to collapse even when the thorax is opened. Adrenaline, ephedrine, and atropine relax bronchi and, in addition, adrenaline causes vasoconstriction of bronchial vessels.

It is important to know that even after the sympathetic and parasympathetic nerves to an organ have been cut that organ seems to have enough inherent nerve control to take care of its autonomic functions. However, if all of the autonomics were permanently and completely interrupted, man would lose his freedom and become as much the victim of his environment as his amphibian ancestors.

Some have attempted to group certain individuals who complain of various functional derangements into classes called *sympathicotonia* (overaction of sympathetics) and *vagotonia* (overaction of parasympathetics). These symptom groups are vague and ill defined.

The *sympathetic* or *energy-spending* system is activated transiently during anger according to Cannon. Arteries are constricted, there is sweating, hair stands on end, "goose flesh" appears, pupils dilate, palpebral fissures widen, and secretions of gastrointestinal glands are inhibited. Through action on the smooth fibers in the spleen, contraction occurs, affording more cells to the circulation (see Chapter 13). The adrenal medulla (chromaffin cells) pours out adrenaline which reinforces sympathetic activities and calls glucose from the liver for use in the active muscles. Cardioaccelerators are stimulated, making the heart beat faster.

It is thought that there are centers in the brain (around the third ventricle and lateral to the infundibulum) which control the entire sympathetic nervous system. These centers are under reflex and psychic control.

The *parasympathetic* or *energy-storing* system helps stabilize overactivities of the sympathetics. Cardioinhibitor nerves slow the heart. Other nerves stimulate the salivary and digestive glands to activity and promote peristalsis. In this way the parasympathetic system helps digest *food*; *it also* aids in excretion (to allow more food to be digested). The sacral parasympathetics empty the rectum and relax the anus and cause contraction of the bladder (detrusor muscle) and relaxation of the sphincter.

Perhaps the autonomics act through chemical substances, *sympathin* and *parasympathin*, which are formed between the nerve ending and the cell. Sympathin possesses the properties of adrenaline (adrenergic); parasympathin, those of acetylcholine (cholinergic).

The Action of Drugs Upon the Autonomic Nervous System

Adrenaline has the same effect as stimulation of the *sympathetics.* Sweating is an exception. Denervated effector organs are sensitized to the action of adrenaline. Vasoconstriction occurs everywhere except in the coronaries, the vessels in the intestines, and perhaps skeletal muscles. Pulmonary vessels are unaffected, but in large doses there is vasocontriction and dilation of bronchioles.

Pilocarpine causes *parasympathetic* effects by acting directly upon *the effector cell. These effects are contraction of pupil, cardiac inhibition,* contraction of smooth muscle is bronchioles and alimentary tract, secretion from salivary, gastric, bronchial, and sweat glands.

Muscarine acts like pilocarpine in most of its effects. In addition, it causes vasodilatation. The action is directly on the effector cell.

Choline and its ester, *acetylcholine*, cause *parasympathetic* effects by acting directly on the effector cell. These effects are cardiac inhibition, contraction of smooth muscle of alimentary canal and bladder wall, secretion of saliva, tears, and sweat, dilation of arterioles and fall in blood pressure. Blood and tissue fluids contain an enzyme, cholinesterase, which inactivates acetylcholine. Physostigmine inhibits the action of cholinesterase; therefore, when given with acetylcholine, the latter's action is greatly intensified.

Physostigmine or *eserine* causes *parasympathetic* effects by inhibiting the action of cholinesterase and so permitting the cholinester liberated at the nerve endings to exert its full effects.

Atropine neutralizes parasympathetic effects by acting directly on the effector cell, thus preventing the action if not the liberation of acetylcholine. It is antagonistic to pilocarpine and muscarine. Thus there is an increase in pulse rate, dilation of pupils, decrease in secretion of saliva

and gastric juice and sweat as well as nasal and bronchial gland secretion It lowers the tone of bronchial and gastrointestinal muscles.

Nicotine is useful in locating ganglion cells which it paralyzes or the synapse between the cell and the preganglionic fiber.

When the body needs *general action*, the *hormones* are liberated rather than the nerve impulses themselves.

Clinical Application

The most direct *application* of this knowledge seems to be in the treatment of peripheral vascular diseases such as Raynaud's, thromboangiitis obliterans (chapter 6), vasospasm following injury to arteries, operations on blood vessels (see Chapter 17), causalgia (Chapter 6), and "phantom limb." This is especially true in Raynaud's disease, where the removal of the sympathetic ganglia will convert a cold, moist, bluish, painful extremity into a warm, dry, painless member.

White believes that if complete sympathetic denervation is accomplished, the vessels are left to the mercy of adrenaline, to which they become hypersensitive.

Furthermore, operations on the sympathetics have been used in the treatment of malignant hypertension (splanchnicotomy), painful states such as angina pectoris (cervical sympathetic neurectomy), pericoronary neurectomy in coronary disease, painful menstruation (presacral neurectomy), and likewise in diseases such as megacolon or Hirschsprung's disease (resection of the inferior mesenteric and superior hypogastric-presacral), and also diseases of the bladder.

A great many minor states that develop as a result of imbalance or overaction of the autonomics may ultimately be relieved by surgery. This field of endeavor is still in its infancy and its application may well be extended to include such intractable states as the chronic arthritides, asthma, irritable colon, and nonspecific ileitis (with constriction).

One is struck with the thought that the granulomatous and fibrotic masses found in certain nonspecific bowel lesions may be initiated in spasm. There is no proof of this theory except the relationship of scleroderma, Raynaud's disease, cardiospasm with achalasia of the esophagus, and regional enteritis and colitis. Some observers maintain that the permanent effects of splanchnicotomy and other operations for malignant hypertension have been found to be no better than after any nonspecific operation.

Horner's Syndrome.—Injury to the cervical sympathetics or invasion by neoplasia may cause a cessation of sympathetic impulses producing Horner's syndrome; namely, contraction of the pupil, enophthalmus, pseudoptosis (that is the upper lid can be raised voluntarily), absence of flushing and sweating in the corresponding side of the face and ear.

Stimulation of the cervical sympathetics cause dilatation of the pupil and flushing and sweating of the face and ear.

Carotid Sinus and Carotid Body.—The physiology of the carotid sinus has been discussed in Chapter 14. The sinus and aortic nerves are important in controlling blood pressure and maintaining the circulation of the brain. Changes from recumbent to the sitting position, loss of fluid or blood volume, etc., result in vasoconstriction and cardioacceleration, elevating blood pressure. Head-down position, vomiting, cough, hydremic plethora, and fear result in vasodilation and cardioinhibition and a fall in blood pressure. The bradycardia is probably by way of the sinus nerve as the vagus is unresponsive to mechanical stimulation. Sometimes paroxysmal tachycardia may be stopped by pressure above the sinus (increasing intraluminal pressure at the bifurcation of the carotid), or nausea and vomiting may be induced with ipecac having the same effect. Only about 30 per cent of normal persons have a carotid sinus which is sensitive to external pressure. In those who are sensitive, a *carotid sinus syndrome* or *vasovagal syncope* (Lewis) may occur. This manifests itself by attacks of dizziness and fainting and sometimes convulsive seizures which result from overactivity of the sinus reflex. During an attack there is a bradycardia and fall in blood pressure. There may be extrasystoles, delay in the auriculoventricular conduction, or complete heart block (Stokes-Adams). Sometimes denervation of the sinus is necessary to ameliorate the symptoms.

The *carotid body* is thought to be derived from the embryonic ganglion cells of the sympathetics. Other theories are that it comes from the epithelium of the pharynx, endothelium, or adventitia of the carotid artery. The function of the carotid body (and also the aortic bodies) is due to the presence within them of chemoreceptors which respond to chemical changes in the blood. These respond to oxygen tension, whereas the respiratory center responds to carbon dioxide tension. They also respond to H ion concentration. Both bodies may be removed without any apparent symptoms. Sometimes carotid body tumors arise. These are usually benign but may be malignant. The diagnosis is based on the palpation of a tumor at the bifurcation and rarely systemic disturbances such as malaise, headaches, and depression. The treatment consists of removal. However, it may be necessary to ligate the common and internal carotids. If a Horner's syndrome or recurrent laryngeal nerve paralysis exists, the growth is probably malignant and has invaded surrounding structures. The mortality (30 per cent) and the morbidity (80 per cent) following surgery is more often due to the ligations rather than to the extirpation of the growth. Therefore, gradual carotid compression is used as a preliminary measure.

Essential Hypertension.—Although the exact cause of essential hypertension is not known, a very logical explanation is based on the work of Goldblatt. He showed by his experiments that any interference

Fig. 199.—Operative technique of thoracolumbar sympathectomy. (Modified from Hinton and Lord.) *A.* Position of the patient on the table. *B.* Incision in the third interspace to get the inferior cervical, first, second and third thoracic ganglia. Incision in the bed of the ninth or tenth rib to get the lower thoracic ganglia, the first and second lumbar, and the greater and lesser and least splanchnic nerves. Many surgeons use an extrapleural type of operation. We have preferred to make the operation a transpleural. *C.* The chest is opened through the eighth interspace, the ribs are spread apart, and the nerves are dissected out after the mediastinal pleura has been opened directly over the nerve bed. *D.* The lower part of the operation requires opening of the diaphragm, and with the wide exposure gained by this maneuver the entire chain may be easily removed, the adrenal may be inspected, and biopsy of the kidney taken. *1*, *2*, and *3* show method of grasping each ganglion and severing of the ganglion from its junction with the intercostal nerve The chain is grasped with a long curved remostat and is carefully dissected from each intercostal artery and vein. Then the communicating rami are divided several millimeters from the ganglia. The greater splanchnic nerve usually has its origin from thoracic ganglia *6*, *7*, *8*, and *9*. It pierces the crus of the diaphragm and joins the anterior end of the celiac ganglion. In its course in the thorax the splanchnic ganglion is usually formed. The lesser splanchnic nerve arises from the gangliated trunk opposite the ninth and tenth ganglia and ends in the celiac plexus. The lowest splanchnic nerve arises from the twelfth thoracic ganglion or from the lesser splanchnic nerve and then pierces the diaphragm and ends in the renal plexus. In this way it is possible to remove the entire thoracic ganglia, the upper two lumbars, and the greater, lesser, and lowest splanchnic nerves. The greater splanchnic nerve is divided at its junction with the celiac ganglia.

with the hemodynamic state of the kidney produces a continuous elevation of blood pressure without evidence of impaired renal excretion. This is now known as the renal humoral theory since many observers believe that the elevated blood pressure is due to an excessive amount of "renin" which reacts with "preangiotonin" to produce "angiotonin," the pressor substance.

Based on this hypothesis and the experimental evidence that electrical stimulation of the splanchnics causes hypertension, presumably producing a renal ischemia, the operation of splanchnicectomy has been used. This then is comparable to sympathectomy in Raynaud's disease for in both there is, for unknown reasons, overactivity of the sympathetics. The operation does produce an increase in renal blood flow and many cures have been produced by the operation before irreversible kidney damage has occurred. The splanchnics (greater, lesser, and least) may be interrupted below the diaphragm (Adson and Craig), above the diaphragm (Peet), and both above and below the diaphragm (Smithwick); there may be almost complete denervation, including the celiac ganglion (Grimson).

Improvement in techniques has made extensive sympathetic ganglionectomy safe. The transthoracic approach is easiest and best. An incision is made in the third interspace posterolaterally, and the upper dorsal ganglia from the third or fourth down are removed. Then another is made in the eighth interspace, and the lower dorsal and upper lumbar ganglia together with the splanchnics may be excised. This is facilitated by incising the diaphragm. Hinton and Lord have done the entire procedure through the bed of the resected ninth or tenth rib. The parietal pleura is reflected from the chest wall, exposing the diaphrgam which is divided, and the retroperitoneal space entered. The chain and the splanchnics are dissected from each intercostal artery and the communicating rami are divided several millimeters from each ganglion. The twelfth ganglion is usually located in the substance of the diaphragm or just above it. The chain is attenuated between the twelfth thoracic and first lumbar ganglia. Following this extensive procedure, orthostatic hypotension is so great that an inflatable "corset" must be used to prevent collapse for a short period. The results are encouraging although permanent cures are not too common and orthostatic hypotension may be a serious handicap.

New Growths.—New growths of the sympathetic ganglia are known as ganglioneuromas. Most of these occur along the route of cervico-thoracico-lumbar chain, some are formed in the suprarenal medulla, and others arise in widely separated ganglia. Most ganglioneuromas are fully differentiated, benign, and do not metastasize; some are partially differentiated and do metastasize, and a few are mixed or pure sympathicoblastoma which are highly malignant and metastasize rapidly.

THE SCALP AND SKULL

The scalp is composed of the following five layers and covers the cranium, which is the bony covering of the brain.

1. The *skin.*
2. The *subcutaneous tissue* is a firm fibrous layer binding the skin to the layer below by strong fibrous septa. In this layer are the blood vessels and nerves.
3. The *aponeurotic layer,* which is in reality the aponeurosis of the occipital frontalis muscle, is loosely applied to the underlying subaponeurotic layer.
4. The *subaponeurotic layer* is made up of loose areolar tissue.
5. The *pericranium* is really the outer covering or periosteum of the skull.

It will be noticed that the first three layers are united as one, but the aponeurotic layer may be easily separated from the cranium. The aponeurotic layer, also known as the galea, is attached to the skull posteriorly (external occipital protuberance), laterally (temporal muscle), and anteriorly (superciliary ridges). This is important, because collections of fluid or pus beneath this layer gravitate to the points of attachment. Furthermore, should a wound extend down to the galea, very little gaping would occur. If, however, the galea were divided transversely, there would not only be gaping, but also avulsion if the force were sufficiently strong. The Indians knew this when they practiced scalping. The blood supply of the scalp is from below upward; consequently, if there is any attachment left, the flap remains viable. This is the reason in brain surgery for making scalp flaps with the lower portion attached.

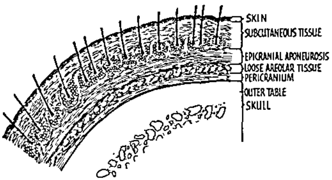

Fig. 200.—The scalp is composed of the following layers: skin; subcutaneous tissue, which contains blood vessels and nerves; aponeurotic layer (*galea aponeurotica, epicranial aponeurosis*), which is the aponeurosis of the occipitofrontalis muscle; the loose subaponeurotic layer; and the pericranium. The outer three layers are adherent to each other.

Injuries of the scalp demand careful inspection for possible skull fracture with brain injury. The hair must be shaved and all foreign bodies carefully removed by frequent washings. Bleeding is usually profuse because the blood vessels in the subcutaneous layer cannot retract and contract as in looser tissues; therefore, hemostasis is accomplished by loose suture.

Infections of the scalp are either localized (carbuncle, furuncle) or diffuse (cellulitis). The treatment is the same as elsewhere, except one must remember that there is a connection between the scalp and the intracranial sinuses through the diploic and emissary veins. Should collections of pus or serum occur beneath the galea, drainage is dependent; that is, at points of attachment (q.v.)..

Tumors and cysts of the scalp are common, especially sebaceous cysts, or wens. These are due to occluded sebaceous ducts and may grow to the size of a hen's egg or larger. They are easily excised. Perhaps the most common tumor is a hemangioma. X-ray films should be made to determine whether these vascular tumors have any intracranial connections (sinus pericranii).

Caput succedaneum is an edema of the scalp of the newborn. It occurs over the part which presented and is probably due to pressure against the rigid external os. *Cephalhematoma* is also seen in the newborn and is due to hemorrhage beneath the pericranium. This swelling is usually limited to one bone, for the pericranium is attached at suture lines. The treatment is entirely conservative for the former and also the latter, unless the hemorrhage remains unabsorbed; in this event, aspiration is done.

The *cranium* is the bony cage within which lies the brain. It is made of membranous bones which heal only by fibrous tissue (because callus swellings would press upon brain tissue). These bones have an outer table covered by pericranium and an inner table lined with the dura mater. Between the tables is the diploe, a loose space containing many communicating veins. The diploic veins carry blood in both directions and emissary veins transport blood from the sinuses to the scalp veins. The sutures of the skull lie *anteriorly* between the frontal and parietal bones, *sagitally* between the parietals, *posteriorly* between the parietals and occipitals, and *laterally* between the parietals and temporals. These sutures are defective at birth—in front and back (anterior and posterior fontanel) and laterally. This arrangement of the six fontanels and the suture lines allows for "molding" during birth and prevents excessive intracranial pressure. The anterior fontanel closes at about 2 years of age; the others, shortly after birth. The obstetrician is able to diagnose fetal position by feeling the fontanels. The suture lines unite at about 40 years of age or thereafter. If because of malnutrition, or disease, or unknown causes, the suture lines and fontanels close prematurely or remain open unusually long, certain *anomalies* present themselves and give various sizes and shapes to the skull. Among these are *microcephaly* (small skull), *oxycephaly* (pointed skull), the large skull of hydrocephalus, etc. Certain bony landmarks of the skull should be remembered for they are frequently used in anatomic descriptions: the bregma, glabella, nasion, inion, and pterion.

Infections of the skull occur as in other bones (see Chapter 21) but are more dangerous because of the possibility of extension into the brain or its coverings. *Osteitis* is a nonspecific infection of bone usually following infection of the scalp and must be relieved by drainage. Large areas of necrotic bone may slough. The process is extremely chronic. The x-ray is invaluable in the diagnosis and shows the amount and progress of the lesion. Tuberculosis is rare but syphilis is common, especially of the con-

genital type (see Chapter 14) and is treated by antisyphilitic remedies. A destructive syphilitic lesion is known as *craniotabes.*

Metabolic and nutritional disorders produce changes in the shape and density of the bone: rickets produces a square or sugar-loaf head, acromegaly, a small head with prominent brows and jaw, while xanthomatosis (Schüller-Christian disease) multiple myeloma, and Ewing's endothelioma produce a moth-eaten appearance of the cranium.

Tumors of the cranium are not uncommon. *Meningiomas* arise from the dura but frequently involve the bone, whereas *osteomas* may arise directly from bone. Both types tend to be slow growing and benign and may be completely removed, relieving brain pressure.

Fig. 201.—Osteoma of the skull.

Injuries of the meninges are described later in the chapter. However, subdural hematoma (pachymeningitis interna hemorrhagica) which results from an injury may produce spasms or convulsions and therefore may require surgical intervention.

Infections of the meninges are known as *meningitis* and if the dura alone is involved (from injury or extension from the skull) it is known as *pachymeningitis.* This must be rare, for the leptomeninges are almost always involved also. Meningitis may be epidemic in type (that is, that caused by the meningococcus). Syphilis, tuberculosis, and toxins produced by a number of organisms may affect the meninges. The treatment is conservative with perhaps occasional spinal drainage and the use of sulfadiazine and penicillin. In tuberculosis the prognosis was

formerly always fatal. Streptomycin offers a much better outlook (see Chapter 8). In other types the outlook is still better, but in none is it real good.

THE MENINGES AND BRAIN

The brain is covered by three membranes known as *meninges*. The outermost is attached to the inner table of the skull and is known as the *dura mater*. It also spreads to form the falx and tentorium. The *arachnoid* covers the brain snugly but does not dip into its convolutions as does the third layer, the *pia mater*, which carries the blood vessels. In some places (as where the arachnoid passes over a gyrus) the pia and arachnoid are connected by dense trabeculae and they appear as a single membrane. The expanded portions are the cisternae which communicate with each other. The larger branches of the arteries and veins of the brain traverse the subarachnoid space. Their walls are directly connected with the subarachnoid trabeculae and are bathed by subarachnoid fluid. Some of the arteries are closely attached to the pia mater. The blood vessels that penetrate the pia are surrounded by perivascular spaces but are not connected with lymph vessels as was formerly thought. They are connected with the subarachnoid space. The finer twigs ramify in the pia before entering the substance of the brain and as they enter they carry sheaths from the pia. The pia and arachnoid together are also known as the *leptomeninges*. The space between the two is known as the subarachnoid space through which flows the cerebrospinal fluid (normally 60 c.c.). This fluid is of the utmost importance, for it forms a layer in the ventricles and subarachnoid space which relieves pressure on the brain within its rigid vault. In coughing, sneezing, injuries, inflammation, and new growths, this is the great equalizer of pressure—until its limits are reached. This fluid is formed chiefly in the *choroid plexuses* which are located in the lateral ventricles and third and fourth ventricles (although some is formed by the cells lining the subarachnoid space). The four places in the brain occupied by these plexuses retains its embryonic character as thin epithelium—lamina epithelialis. The pia mater which covers this epithelium is very vascular and is closely joined to the lamina epithelialis, forming the tela choroidea. The tela choroidea is irregular and folded, protruding into the ventricle so that a great free surface full of blood vessels is exposed to the ventricles. The epithelium is different from the ependymal cells which line the ventricles. It is cuboidal and is composed of one layer. These cells store dyes as do the fixed macrophages in the perivascular connective tissue. The leptomeninges have no such function. The subarachnoid space is carried outward for a short distance on the nerves in connection with their arachnoidal sheaths and communicates with the lymph channels of the nerves. This is especially true in the oldfactory, optic, and acoustic nerves. Some observers believe that there is a communication between the subarachnoid space and the lymph vessels of the nasal mucous membranes. Dandy believed that cerebrospinal fluid is absorbed from the entire subarachnoid space in to the capillaries of the pia arachnoid and denied the existence of arachnoidal villi or pacchionian granulations. His experiments show that when the cerebral hemispheres are separated from the longitudinal and transverse sinuses on both sides, leaving only the rolandic vein attached (no pacchionian granulations), absorption of cerebrospinal fluid was unimpaired.

The vessel walls and the pia must be traversed for fluid to get out (Drinker and Fields). This double membrane may account for the high degree of impermeability of the choroid plexus not only to much of the blood proteins, but to other more diffusable substances as well. Although true solutions pass readily, colloids may go through slowly and particulate matter does not pass at all. The flow is through the foramen of Monro to the third ventricle and from here through the foramen of Magendie and the foramina of Luschka through the cisternae, which lie in the subarachnoid space. Here it is absorbed by the blood stream in the venous sinuses (sagittal, transverse, and

cavernous), through the arachnoidal villi, due to the greater osmotic pressure of the blood, the higher hydrostatic pressure in the subarachnoid space, and the thinness of these membranes. A small amount of cerebrospinal fluid is absorbed by the true lymphatics along nerves and blood vessels and also by the capillaries of the pia arachnoid similar to that of fluids elsewhere in the body. This is the fluid circulation of the brain and spinal cord and is the only one except the blood, for there are no demonstrable lymphatics in the brain, although there are some in the perineural spaces. The brain is guarded against excessively high blood pressure by the carotid sinus mechanism at the "vascular gateway." Changes in velocity supply more blood and O_2 per minute—great increases in volume do not normally occur in the cranial cavity which is closed. About 800 c.c. of blood pass through the brain each minute. The cerebral circulation must be kept constant. Wide fluctuations must not occur and therefore vascular regulation falls upon the liver and spleen (Chapter 22) and kidneys (Chapter 23).

There is much controversy concerning the physiology of the cerebrospinal fluid. This is particularly true concerning its mode of production.

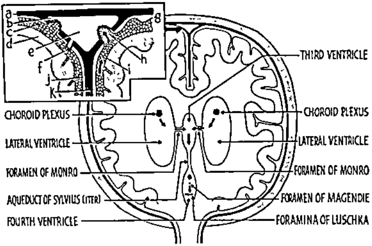

Fig. 202.—Circulation of cerebrospinal fluid. Diagram illustrating the ventricles of the brain and the circulation of the spinal fluid. The fluid is produced by the choroid plexuses in the lateral ventricles and passed through the foramina of Monro (*interventriculars*) to the third ventricle and thence through the aqueduct of Sylvius (*iter, or aqueducts cerebri*) to the fourth ventricle, where more fluid is added by a choroid plexus. From here the fluid flows through the median foramen of Magendie (*appertura medialis ventriculi quarti*) and the foramina of Luschka into the cisterna magna and then into the subarachnoid space of the spinal canal. Here there are some addition to the fluid (from cells) and some absorption through arachnoidal villi. Then the fluid returns to the cerebral subarachnoid space through other cisternae. Absorption takes place into the blood stream because of the greater hydrostatic pressure of the cerebrospinal fluid and the higher osmotic pressure of the blood. There are normally about 60 to 150 c.c. of fluid which contains 16 to 35 mg. of protein (as compared with 6300 to 8500 mg. in blood plasma). *a*, dura mater; *b*, parasinoidal sinus; *c*, subarachnoid space; d, cerebral cortex; *e*, superior sagittal sinus; *f*, cerebral vein; *g*, arachnoid mater; *h*, arachnoidal villus; *i*, pia mater; *j*, subdural space; *k*, falx.

The cerebrospinal fluid forms a column without valves about 600 mm. long in the average man. Its hydrostatic pressure is about 10 mm. Hg (lying down). The cerebral sinus pressure is about 6 to 8 mm. Hg, and the latter varies with the former. The blood pressure in the cerebral arteries is about 100 mm. Hg systolic and 65 mm. Hg diastolic. The capillary pressure is about 13 mm. Hg. On standing, the venous pressure may be zero. Changes in pressure in the right auricle are transmitted to the jugulars and so to the intracranial veins. Also respiration affects the intravenous pressure, causing an increase during expiration and a decrease during inspiration.

The osmotic pressure of the cerebrospinal fluid is not definitely known. Teschler and Fremont Smith say that the cerebrospinal fluid is in osmotic equilibrium with the

blood. Freezing points of blood serum and cerebrospinal fluid are the same. Hamilton states that the total electrolyte concentrations of serum and spinal fluid are the same.

Plasma exerts an osmotic pressure against isotonic salt solution in equilibrium with it of about 25 mm. Hg. Five millimeters of this pressure difference are due to the unequal distribution of electrolytes in accordance with Donnan's law and 20 mm. to the plasma proteins. Since the ependyma (ventricles and arachnoid) is impermeable to both electrolytes and proteins except at the tela choroidea, it is difficult to estimate such pressure in vivo and in vitro. Since the fluid resembles blood serum most closely, it is likely to have a comparable osmotic pressure. Although the protein content is low as compared with serum, it is not as important as in the blood capillaries because the electrolytes as well as proteins exert an effective osmotic pressure. This is due to the double membrane over the choroid plexus, making it less permeable to both. The osmotic pressure then is about 23 to 25 mm. Hg.

The osmotic pressure in the capillaries is about 25 mm. Hg and in the cerebral sinuses, 26 mm. Hg. Therefore, cerebrospinal fluid may reach the ventricles as a dialysate if it is in equilibrium with blood plasma or as an ultrafiltrate if the hydrostatic pressures are as depicted. The various pressures would be as follows:

	CEREBRAL SINUSES	C-SP. FLUID	CAPILLARIES
H =	13 mm. Hg	10 mm. Hg	6-8 mm. Hg
O =	25 mm. Hg	23-35 mm. Hg	26 mm. Hg

The osmotic pressure of lymph is about 18 mm. Hg, and its hydrostatic pressure varies with surrounding tissue space pressure.

Under normal conditions, then, *all attraction of fluid is toward the ventricles and then into the cerebral sinuses.*

This does not explain why cerebrospinal fluid will continue to form even in the face of increased intraventricular pressure. Since the pressure differences are so small and since the choroid is relatively impermeable to many substances, most observers believe the cerebrospinal fluid to be a secretion the direct product of the tela chorioidea. Flexner studied the problem on the basis of free energy change and concluded that the cerebrospinal fluid is to be considered a secretion; that is, the cells must do work in the formation of the fluid. Spinal fluid is reformed in three to five hours after it has been removed. The introduction of concentrated glucose into the venous system increases osmotic pressure within the venous sinuses and therefore attracts spinal fluid more quickly into them. Since fluid is attracted into the blood stream all over the body (see Chapter 11), the osmotic effect is soon lost.

Lumbar puncture reduces cisternal pressure in cases of increased intracranial pressure; at the same time the intraventricular pressure may remain disproportionately high, resulting in a temporary internal hydrocephalus. This may result in herniation of the medulla into the foramen magnum, causing embarrassment to the respiratory and cardiac centers.

Anomalies of the Skull and Meninges

Sometimes nature fails to close the skull and meninges at birth. This results in a protrusion of intracranial contents through the defect (cephalocele). It is usually in the median line, in the frontal or occipital region, or it may occur at the inner angle of the orbit. If the protrusion is composed of meninges and fluid, it is called a *meningocele;* if it contains brain tissue, it is known as an *encephalocele.* The treatment for these anomalies is surgical reduction and imbrication of the sac. In en-

cephalocele, due to the increase in intracranial pressure, the prognosis is guarded. In either case hydrocephalus may occur (see below).

Hydrocephalus is, as its name implies, an excess of cerebrospinal fluid within the ventricles (internal hydrocephalus) or in the subarachnoid

Fig. 203.—Infant with cephalocele (meningocele).

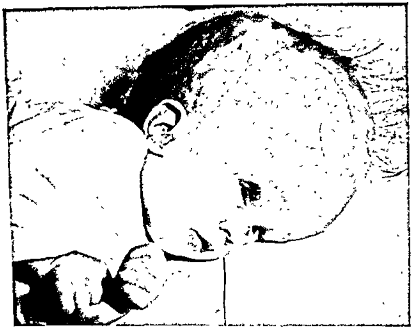

Fig. 204.—Congenital internal hydrocephalus. Note the flexed arms (this position is typical).

space (external hydrocephalus). The former is by far the more common and is either congenital (obstructions in the interventricular system) or acquired (obstructions due to new growths, meningitis, or arachnoiditis). We may well imagine that internal hydrocephalus could result from an overproduction of fluid. This is not the case, however, for

production is normal, but absorption is limited or absent. In any event, the cranial vault becomes enlarged, the sutures are widened, and the fontanels bulge. Whereas mild hydrocephalus is not incompatible with life or high mental development, the more severe types are. Such children rarely live over two or three years, and if they do, they are more or less helpless, mentally and physically. Treatment in the congenital types consists of needle puncture through the sagittal sinus into the subarachnoid space. External types of hydrocephalus are usually due to injuries or congenital anomalies and are localized. Their production is due to an interference of fluid absorption by the pia arachnoid capillaries in the involved area.

Function of the Brain

The brain is the great "telephone exchange" for the many "lines" that carry messages to and from every nook and cranny of the entire body. Within itself there must not only be ingoing and outgoing

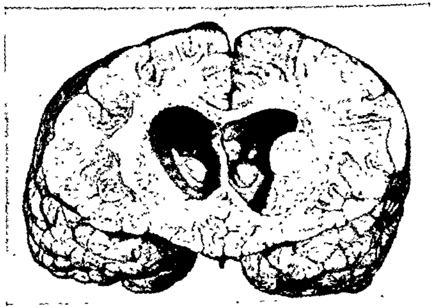

Fig. 205.—Internal hydrocephalus in a 19-year-old child, due to blockage of the aqueduct of Sylvius. The primary tumor was in the midbrain.

stations, but there must be communications between these. Also, the so-called silent areas, which may be termed the storehouse of impulses (memory) and perhaps of emotions as well, must be in intimate touch with the entire system. Nor is this all, for the autonomics (sympathetics and parasympathetics), although altogether outgoing and not under voluntary control, are nevertheless affected by all other divisions of this complex system and in turn may profoundly affect all other "departments."

The brain, then, receives impulses through the sensory nerves, which relay them to the afferent or sensory (dorsal and lateral) tracts in the white matter of the spinal cord, which in turn "deposit them" in the parietal lobes (post-Rolandic area) of the brain. This informs the body

of all of its contacts with the outside world, pleasurable or otherwise, and of its muscular movements (deep sensations). The senses of sight, smell, taste, and hearing are carried to the occipital, frontal, and temporal lobes, respectively, by special nerves (the cranial nerves, q.v.). Some of these impulses will be *stored in memory, others will be relayed to* special centers; still others may evoke responses in the higher centers of emotion or in the autonomies. Most of the impulses will be relayed to the frontal lobe (pre-Rolandic or motor area). From here they will go down the cord (anterior and lateral tracts) to find expression in voluntary movement. The coordinated muscular movements are controlled also in an involuntary manner through the cerebellar tracts, which carry impulses to the cerebellum from which messages are relayed to the motor area. Therefore, roughly, there are nerves that are sensory (telling us of our outer and inner contacts, or sensations); then there is a system that acts or responds to these stimuli in a voluntary way (muscle action) or involuntary way (autonomic action; then there is a coordinating muscle system that allows us to move and act. All of the systems intercommunicate so that there may be immediate action when necessary. Or the impulses may be stored for future use in the great memory zones (knowledge), where they may be unified, rearranged, and synthesized in a logical manner (learning or wisdom), thereby elevating man, *Homo sapiens,* above the mental level of lower animals.

Routine actions which do not need the help of the brain are handled in the spinal cord as *reflex actions.* These, together with special functions of the peripheral nerves, are discussed later in this chapter.

Areas of Localization

It is but a short time since modern surgeons first dared to enter the cranial vault—yet the operation of trephining is ancient. Research has made it possible to locate the functional areas of the brain. These cannot be definitely outlined, for the boundaries shade off into surrounding zones, but the areas are known sufficiently accurately to explain the physiology of normal activities and the symptoms and signs of pathological ones. The following areas are recognized:

Frontal Lobes.—

1. Motor area (precentral gyrus—pre-Rolandic area)—muscle movements.

2. Silent area—memory, orientation, emotional control, and association of ideas. Especially the left frontal lobe. Prefrontal lobotomy is done in those who lose *their normal traits.*

Parietal Lobes.—

1. Sensory area (postcentral gyrus—post-Rolandic area).

2. Somesthetic area, or stereognostic areas—spatial recognition, recognition of relative intensity, recognition of similarity and difference. If diseased, astereognosis results.

Temporal Lobes.—

1. Centers for taste and smell.

2. Optic tracts sweep by. When a tract is injured, hemianopia results.

3. Auditory area, with speech center on left side in right-handed people. They are said to be "left-brained." Lesions here produce sensory or motor *aphasias*. In addition, lesions of the temporal lobes may produce auditory, olfactory, and gustatory disorders. There may be dreamy states and disturbances of memory; sometimes epileptiform seizures which are preceded by aura of smell, taste, or hearing.

Occipital Lobes.—

1. Visuosensory area.

2. Visuopsychic area—visual sensations interpreted.

3. Memory images of speech are located here. If the area is diseased, *alexia* occurs (inability to read although letters and words are seen). Motor speech is preserved and understanding is unimpaired.

The most important from the standpoint of the surgeon are the pre-Rolandic and post-Rolandic areas. The pre-Rolandic area is a motor area, with the center for the muscles of the face at the lowermost (inferior) portion of the anterior central gyrus and the center for the muscles of the extremities at the superior limits of the gyrus. The post-Rolandic area is a sensory area and, if diseased, precludes or alters such stimuli as occur from pain, heat, cold, etc.

Cerebellar lesions produce *ataxia,* lack of muscle sense, staggering gait, and hypotonia of the muscles.

Diseases and Injuries of the Brain

Pressure Symptoms.—Symptoms and signs of brain disease arise principally from an *increase* in *intracranial pressure.* These are known as *pressure symptoms.* They vary not only with the degree of pressure, but also with the rapidity with which they occur. Thus in cranial injuries where the increase in intracranial pressure is sudden, symptoms will be severe and ominous, whereas the same degree of pressure evolved slowly will evoke only moderate symptoms. This is due to adjustments of tissues to a diminishing blood supply compensated by collateral vascularity where possible and decreased tissue metabolism. This same observation pertains to any organ or tissue as illustrated in gradual occlusion of the common carotid, hepatic, and abdominal aorta with minimal changes in the brain, liver, and lower extremities as opposed to abrupt interruptions with resulting necroses. The triad of symptoms upon which diagnosis is most commonly made is headache, vomiting, and a choked disc. Other symptoms are less constant.

1. *Headache* is severe and intractable (organic headache). It may ameliorate at times but does not disappear.

2. *Vomiting* is unrelated to food and is usually projectile in type.

3. A *choked disc* results from an interference with the venous return and *the circulation of the cerebrospinal fluid. There is an edema of the* optic nerve head, papilledema, which obliterates its margins. This is seen through the ophthalmoscope and is an invaluable sign.

4. A less constant pressure symptom is a *change in the reflexes.* This is always present in motor area disease. Often the growth may *stimulate*

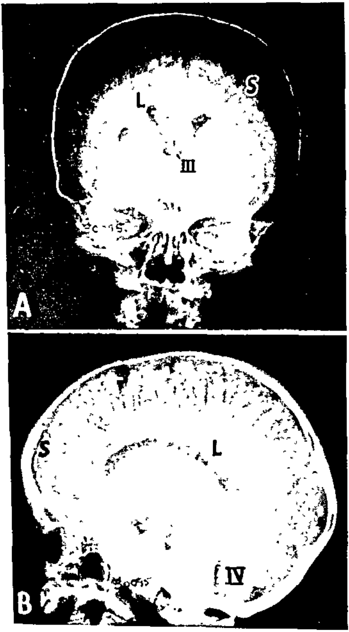

Fig. 206.—*A*, Encephalogram visualizing the lateral ventricles (L), the third ventricle (III), and the subarachnoid space (S). *B*, Encephalogram visualizing the lateral ventricle (L), the fourth ventricle (4), and the subarachnoid space (S). Air was injected into the subarachnoid space through lumbar puncture.

by local irritation the motor zone, producing *convulsions* or *spasms*, either in one set of muscles (jacksonian contractions) or over the entire body.

5. The function of the brain may be so *depressed* as to produce *paralyses*. These are usually limited but may involve a whole side of the body. These symptoms and signs suggest brain disease. By studying them carefully, together with the more definite localizing signs which may be present, the location of the area involved may be surmised. In addition, such measures as *ventriculography* (injection of air into the ventricles and x-ray), spinal and cisternal punctures for pressure reading, and cell counts, protein, and sugar content help determine the presence and position of growths. At operation a more precise location of cerebral tumors may be obtained by means of radioactive phosphorus and a special Geiger-Müller counter (Selverstone and associates).

Head Injuries.—The most common injury to the head is a contusion, with or without skull fracture. If the scalp is lacerated, it will demand the same treatment as has previously been described for other wounds. However, the hair must be carefully shaved. Bleeding is profuse, because of the arrangement of vessels in the subcutaneous layer. The important consideration is not the scalp wound, or the extent of the fracture, which may be present; it is the probability of injury to the brain.

Classification of Fractures of the Skull.—Classification is necessary to explain certain symptoms and signs and types of treatment. The fracture per se is relatively unimportant and will heal; the injuries beneath the skull (in the brain) determine the outcome of the injury.

A number of different criteria are used for the classification of skull fractures:

1. Method of production; most fractures of skull result from tension that is tearing apart rather than compression
   a. Bursting fracture (skull squeezed between two objects)
   b. Indented fracture (skull fractured by blunt force)
   c. Penetrating fracture (skull fractured by a bullet or sharp instrument)
   d. Expansile fracture (skull fractured by a bullet or explosive which causes expansion as it passes through the head)

2. Nature of the break
   a. Fissured (single line)
   b. Comminuted (many radiating lines)
   c. Depressed (skull is dented)

3. Anatomic location
   a. Base
      (1) Anterior fossa
      (2) Middle fossa
      (3) Posterior fossa

b. Vault
   (1) Frontal region
   (2) Parietal region
   (3) Occipital region

4. Degree of injury to overlying scalp
   a. Simple
   b. Compound

Cerebral Compression.—The brain lies in a rigid case. When swelling or extravasation occurs, brain tissue becomes compressed. When it is squeezed, it loses its blood supply, and anemia of the brain follows. This is known as *cerebral compression.* Its chief causes are (1) edema, (2) hemorrhage, (3) inflammation or suppuration, (4) new growths, (5) foreign bodies.

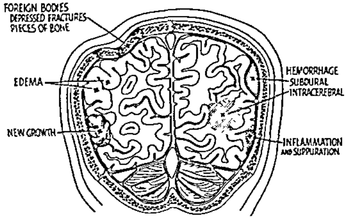

Fig. 207.—Diagram illustrating some causes of cerebral compression. The acute types are caused by hemorrhage, or edema, or both) or by foreign bodies; the less acute, by inflammation; and the chronic, by new growths. Symptoms appear immediately in the acute type, late in the chronic types.

These causes may be present singly but as a rule it is a combination of morbid changes that produces cerebral injury and compression. Swelling is more often due to blood than edema. In fact, the latter is difficult to demonstrate at necropsy and there is actually often less fluod in a traumatized brain than in a normal one.

Acceleration and deceleration of the head and direct compression by deformation of the skull may result in increased intracranial pressure waves. Deceleration is due to indirect injury. Mass movements of the brain occur when the head is free to move. Oxidative processes are about normal in injured brains except in areas of contusion and laceration. This is also true in simple depressed fractures where pathological changes are caused by the original blow and not by irritation of the overlying depressed bone.

Contrecoup or indirect injures imply that the brain may be injured on the opposite side of the point of impact. Injuries to the brain on the

same side of the external blow are known as coup injuries. These injuries to the brain may occur without influence of skull fractures, especially when the head in motion strikes a stationary object. The lesion is not always directly opposite to the impact. Since the occipital region is rarely involved by contrecoup damage, the anatomical relation of the brain and the portion of the skull proximate to it is probably responsible for the nature and distribution of the lesion. The mechanism is probably a wave of force transmitted directly through the brain, thrusting it to the opposite side and producing injuries along the route of this force. When blood does not reach the brain, its function is severely impaired in the higher centers and also in the medulla. This impairment will be greater in conditions which come on rapidly and less severe (though equally disabling) in new growths which grow slowly enough to allow the brain to adjust to the increasing pressure.

Degrees of Cerebral Injury.—The following injuries may occur: (1) *Concussion*—a shaking-up of the brain, with little or no organic change; that can be grossly demonstrated. However, significant alterations in arrangement, shape, and size of Nissl bodies have been observed in experimental animals, without showing any change in nerve fibers or myelin sheaths. In less than twenty-four hours after concussion, chromatolysis of certain neurons begins (chiefly the lateral vestibular nuclei and the large neurons of the tegmentum of the midbrain, pons, and reticular formation of the medulla oblongata). In two days many cells showed great changes which progressed to complete destruction by the eighth day, and these changes were different from those observed after sectioning a nerve or in anoxia. Primary afferent and primary efferent neurons of the cranial ganglia and cranial nerve nuclei are not often affected. Hemorrhage is not encountered but some observers report changes characteristic of anoxemia. This, coupled with a rise in intracranial pressure above systolic pressure (in dogs), may explain mild cases of "punch drunkenness" or severe cases of concussion coma. (2) *Contusion*—a severe blow to the brain, producing a rupture of the smaller vessels, with resulting edema and hemorrhage. (3) *Laceration*—a tearing of the brain tissue, with injury to nerve cells and much hemorrhage. (4) Combinations of the foregoing.

Symptoms and Signs.—The symptoms produced will vary with the degree of cerebral injury or compression.

When a patient sustains a severe head injury, he may first go into a state of shock (see Chapter 14). Later he will react from this state, and as intracranial pressure increases, his vital centers will be stimulated. If this pressure continues, the vital centers will become inhibited, but if it ameliorates, they may return to their normal activity. Careful and close observation of the patient will reveal the degree of injury, the prognosis, and indications for treatment. The following information is vital: (1) state of consciousness; (2) sphincteric control; (3) tempera-

ture; (4) pulse; (5) respiration; (6) blood pressure. This information should be carefully charted at half-hour intervals so that trends may be evaluated.

1. *Stage of Shock:* If shock is profound, there may be unconsciousness and lack of sphincteric control. Usually this is not true. It is difficult to separate concussion and contusion of the brain from cerebral shock. In civilian practice shock is commonly encountered due to brain injury or associated trauma (see Chapter 14).

The temperature in shock will be subnormal. The pulse will be rapid and thready (130-150). The respiration will be shallow and rapid (30-40). The blood pressure will be low (90/40).

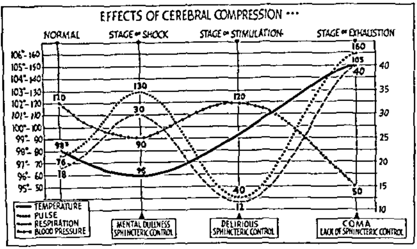

Fig. 208.—Effects of acute cerebral compression as seen after skull fracture. The patient is usually brought to the hospital in a state of shock. After one to two hours there is a reaction, with symptoms of cerebral compression. These are at first stimulated to the vital centers, but if pressure continues the centers fail.

2. *Stage of Reaction:* Soon there will be a reaction, and if intracranial pressure is increasing, the vital centers will be stimulated in an attempt to keep pace with the increase. The cardioinhibitory center will be stimulated (bradycardia) and the pulse will be very slow (40 to 60) and regular. The respiratory center will be stimulated and respirations will be deep, slow (12-15), and regular. The vasomotor center will be stimulated and the blood pressure will go up say to 120 systolic over 80 diastolic. In addition, the higher centers may be stimulated, making the patient restless and delirious.

3. *Stage of Depression:* If the intracranial pressure continues to increase, the centers become depressed and finally paralyzed. This is due to the fact that this pressure ultimately equals the systolic blood pressure (because of a decreased absorption by the occluded venous sinuses and increased filtration from the choroid plexuses), and this prevents blood from reaching the brain. The cardioinhibitory center will not exert its control, and the pulse will become rapid and irregular. (Great variability in

pulse rate is a bad prognostic sign.) The respirations will be shallow, rapid, and irregular, or Cheyne-Stokes in type.

Cheyne-Stokes respiration in increased intracranial pressure has been explained by Cushing as follows: When the increase in intracranial pressure is greater than the arterial blood pressure, there results an anemia of the brain which suspends the activity of the respiratory center. At first this increased intracranial pressure stimulates the vasomotor center, causing a rise in blood pressure, which causes a more rapid flow of blood to the medulla and resuscitation of the respiratory center. This steplike series of increases gives rise to the period of breathing and cessation of breathing. No doubt the accumulation of CO_2 aids in stimulating the respiratory center. Henderson believes that the periods of deep breathing may cause a diminished CO_2 (acarbia) in the blood. Acarbia causes not only apnea, but also rapid heart beat, fall in blood pressure, and shock. Perhaps CO_2 may be necessary to keep up the normal irritability of the vasomotor center.

The respiratory center is normally under the control of:

1. Chemical influences. Carbon dioxide is probably the controlling factor; however, lack of oxygen may excite the center also. In Chapter 12 we have seen that the pH of the blood may influence the center. Carbon dioxide excess increases chiefly the *depth* of breathing.

2. Nervous stimuli.

a. These are carried chiefly by the vagi, which act to offset any changes in respiration. When the lungs are distended with air, afferent vagal impulses inhibit the automatic action of the center and arrest inspiration, thereby bringing on expiration; when the lungs are empty of air, these impulses stop, thereby arresting expiration and permitting inspiration to occur (Hering-Breuer reflex). Therefore, the vagi influence both the *rate* and *depth* of breathing.

b. Sensory stimuli for any portion of the body carried over sensory nerves may have a *pressor* effect, causing quicker and stronger inspiration, or a *depressor* effect, causing respirations to become slower, or more feeble, or even to cease entirely.

c. Voluntary control may be exerted over respiratory movements.

d. Carotid sinus impulses arise from changes in blood pressure. A low oxygen content of arterial blood may stimulate the center. CO_2 affects the carotid body as do oxygen lack and H ion concentration. As arterial pressure rises, depth of respiration decreases, and if it continues, there is apnea.

Blood pressure will fall rapidly and progressively. As increase in intracranial pressure occurs, the temperature increases. This is difficult to explain, but it is probably due to an injury of the heat-regulating center. If the patient has no control of the sphincters, and has lost consciousness, lying in a stupor or coma, the higher centers are also paralyzed. Should the intracranial pressure decrease, the blood pressure,

pulse, respiration, temperature, and mental state will return toward normal. This information is far more valuable than that obtained from spinal punctures (which may increase the bleeding) or from x-rays, which may be done later, as a matter of record.

Prognosis.—Seventy per cent of all head injuries will get well if treated expectantly. Twenty per cent will die in spite of anything we may do because of extensive brain lacerations. Ten per cent need active aid.

Treatment of Head Injuries.—The patient should not be moved to be x-rayed for two or three days. The reason is that moving him may increase the shock and finding the fracture offers little help in treatment. It should be done before the patient leaves the hospital. Also, lumbar punctures should not be done. There has been much argument about the value of this. If the brain is torn and bleeding, and if it is being carefully compressed by the cerebrospinal fluid, lumbar puncture will relieve the compression but is apt to increase the hemorrhage, or further traumatize the brain by causing it to jam against the foramen magnum, or increase the shock.

Spinal fluid pressure is an indicator of cerebral compression. However, there may be great elevations in pressure with little interference with function and therefore few symptoms, or there may be small increases in pressure with much interference of function and many symptoms. In a way, spinal fluid pressure is comparable to the systemic blood pressure in this regard. Consequently, a careful study of cerebral symptoms is perhaps more important than the knowledge of cerebrospinal pressure. The presence of blood implies serious brain injury and this is easily ascertained by the symptoms and signs. Large doses of morphine or barbiturates should not be given, for these drugs decrease and depress the respiration and clouds the clinical picture, so that it may be difficult to determine whether the patient is in a state of unconsciousness or not. If restless, the patient may be given small doses of rectal ether or, better yet, paraldehyde, 10 to 20 c.c., per rectum. Hypertonic dextrose solutions, given intravenously, are advocated by many. However, Dandy, Masserman, and others oppose its use. Glucose and sodium chloride are stored in the brain. Sucrose is rapidly excreted and carries water with it. Opposition to the use of concentrated (50 per cent) glucose solution is based on the fact that it causes a primary fall in cerebrospinal pressure, followed by a secondary rise. There are also headache and adverse chemical reactions in the brain. Also hypertonic solutions are known to produce foamy swelling of the lining cells of the renal convoluted tubules. Some believe that edema is actually increased. In Chapter 11, The Interchange of Body Fluids, we have observed that fluid is drawn into the blood stream by hypertonic solutions. This temporary hydremia is relieved by increased diuresis, with a net loss of water to the body, thereby further increasing the density of the blood. Thus more fluid is removed from the tissues and consequently more from the cerebrospinal

fluid. Ultimately dehydration of the brain will occur. Dehydration reverses pressures in the cerebrospinal fluid and blood, lowering the former below the latter. This would cause any fluid produced by the choroid plexus to be promptly absorbed not by hydrostatic but by osmotic factors. Thus the ventricles are rendered empty for variable periods, theoretically permitting the brain to expand.

Brain cells need salt, glucose, and oxygen for their metabolism. If dehydration produces a stagnant anoxemia, as it usually does, there will result cerebral anoxia and increased permeability to uninjured, as well as to injured capillaries. The injured leaky capillaries, however, may permit the hypertonic solutions to enter the intercellular spaces and thereby produce more edema. Filtration and absorption in the brain may be explained in part by Starling's theory. After trauma, there is capillary dilatation with leakage of plasma. This in itself draws cerebrospinal fluid into the intercellular spaces. Since no lymph spaces are present, absorption must occur through the arachnoidal villi into the cerebral sinuses. Stasis occurs due to venous compression and causes more plasma to leave the vessels, thereby increasing the edema.

Perhaps a better plan of treatment than the use of hypertonic glucose is repeated transfusion of blood plasma, which has a higher osmotic pressure and will not leave the capillaries so readily. This may cause a more rapid absorption of the cerebral edema. Dehydration is not produced either by withholding fluid or by using hypertonic solutions, nor is hydremia induced by too much fluid. We usually give 500 c.c. of physiological saline by hypodermoclysis, 500 c.c. of 5 per cent glucose in distilled water intravenously during the course of twenty-four hours in an adult of average weight. We are governed by the same factors of hydration as set forth in Chapter 11 plus signs of intracranial pressure plus indications for whole blood as determined by the hematocrit and plasma protein determinations which, though transient signs, are helpful guides. Drugs are used to relieve pain and induce rest but must not be strong enough to produce unconsciousness or depress the respiratory center, for death may occur from respiratory failure. If a patient lives eight to ten hours after the injury, he will probably recover.

Other aids in treatment include the following:

(1) Elevation of the head of the bed which reduces venous, sinus, and cerebrospinal fluid pressure and also allows for pooling of blood in the splanchnic area and lower extremities. This may reduce intracranial pressure.

(2) Administration of oxygen.

(3) Anchoring a catheter and recording hourly output and specific gravity. This is the most reliable sign for fluid requirements when used with other clinical signs of water balance as set forth in Chapter 11.

(4) Watchful inactivity—the guiding philosophy in most head injuries.

(5) No intravenous or subcutaneous fluid if the patient is conscious and can take the fluid and food by mouth.
